Otitis Media

Stephen I. Pelton

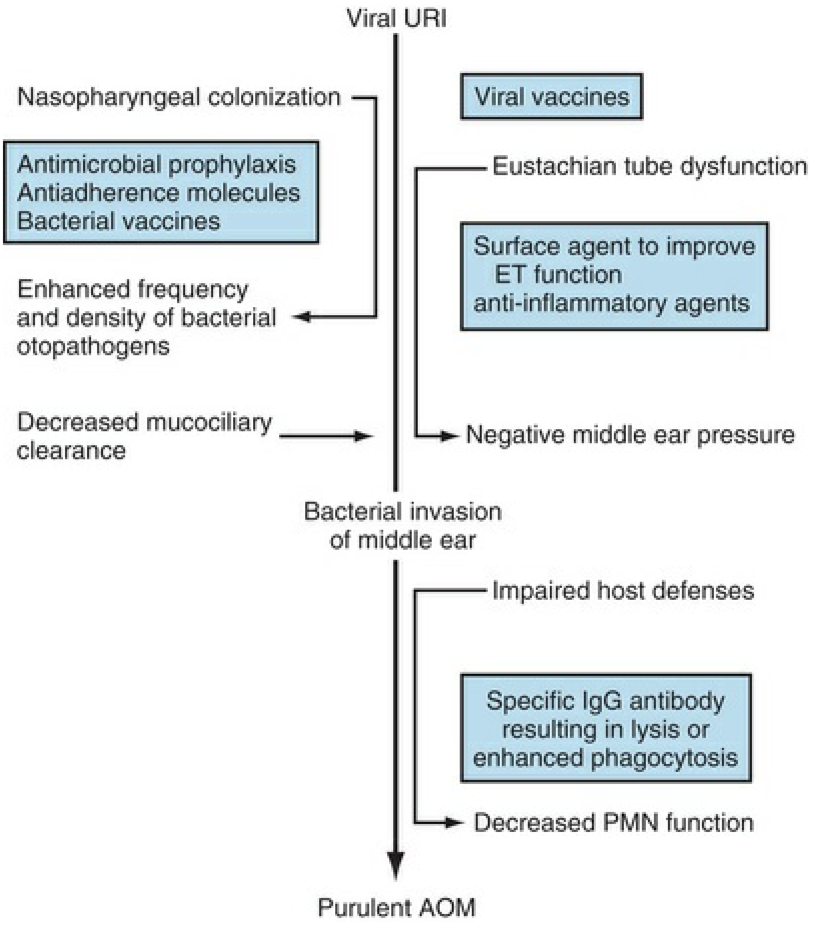
Otitis media is a disease of early childhood. Its relevance to child health in high-income countries has evolved from concern about suppurative complications to concern about prolonged conductive hearing loss, language, and cognitive delays. In low-income settings, acute otitis media (AOM) remains a source of contiguous or hematogenous spread to the mastoids or central nervous system, with potentially fatal outcomes. Although incidence is declining, AOM results in more than 12 million antibiotic prescriptions annually and causes significant family disruption.[1] The impact of universal administration of pneumococcal conjugate vaccine (PCV) on the incidence of AOM and concerns about widespread use of antibiotics for treatment have prompt ongoing re-evaluation of optimal strategies for management.[2]

Acute Otitis Media

Pathogenesis

AOM usually is considered to be a bacterial infection because bacterial otopathogens are isolated from middle ear culture in 70% of cases.[3] AOM usually is a coinfection, with a viral upper respiratory tract infection (URI) enhancing the ability of bacterial otopathogens from the nasopharynx to gain access to the middle ear. Respiratory tract viruses alone occasionally cause AOM (2% to 20%) as proved by tympanocentesis.[4] Eustachian tube dysfunction (i.e., tympanometric measurement of negative pressure) occurs in

75% of children with a viral URI and is a major contributing factor to the development of bacterial AOM.[5] Influenza A infection can suppress neutrophil function[6] and macrophage recruitment, and it likely contributes to the high attack rate for AOM observed among children with influenza A infection.[7] Viral URI in animal models and observed in children enhances the frequency and density of nasopharyngeal colonization with otopathogens.[8–10] Fig. 29.1 synthesizes the important pathophysiologic mechanisms.



Viral URI
Nasopharyngeal colonization
Viral vaccines
Antimicrobial prophylaxis
Antiadherence molecules
Bacterial vaccines
Eustachian tube dysfunction
Surface agent to improve ET function
anti-inflammatory agents
Enhanced frequency and density of bacterial otopathogens
Decreased mucociliary clearance
Negative middle ear pressure
Bacterial invasion of middle ear
Impaired host defenses
Specific IgG antibody resulting in lysis or enhanced phagocytosis
Decreased PMN function
Purulent AOM

FIGURE 29.1 Schema of events in viral-bacterial pathogenesis of acute otitis media (AOM), with potential intervention strategies (shown in boxes). ET, endotracheal tube; Ig, immunoglobulin; PMN, polymorphonuclear leukocyte; URI, upper respiratory tract infection.

Microbiology and Antimicrobial Susceptibility

A limited number of viral (Table 29.1)[4] and bacterial pathogens are recovered from culture of middle ear fluid. Four bacterial otopathogens—*Streptococcus pneumoniae*, nontypeable *Haemophilus influenzae* (NTHi), *Moraxella catarrhalis,* and *Streptococcus pyogenes* (i.e., group A *Streptococcus* [GAS])—consistently are recovered from children with AOM. Although the proportion of disease due to each pathogen varies with geography and age, remarkable consistency has been observed in microbiologic studies of symptomatic middle ear disease.

TABLE 29.1

Virus Detected Alone or in Combination With Bacterial Pathogens in Middle Ear Fluid in 128 Children With Acute Otitis Media

Virus	No. of Viruses	% Of Total Virus Count
Respiratory syncytial virus	72	49
Parainfluenza virus (types 1, 2, and 3)	20	13.6
Influenza virus (A and B)	19	12.9
Enterovirus	10	6.8
Rhinovirus	10	6.8
Cytomegalovirus	8	5.4
Adenovirus	7	4.8
Herpes simplex virus	1	0.7
Total	147	100

Modified from Chonmaitree T. Viral and bacterial interaction in acute otitis media. Pediatr Infect Dis J 2000;19:S24–S30.

Jacobs and associates[3] described otopathogens recovered from 917 episodes of AOM in Eastern European, Israeli, and US children in 1994 and 1995. After the US introduction of the 7-valent pneumococcal conjugate vaccine (PCV7) in 2000 and the 13-valent vaccine (PCV13) in 2013, the microbiology of AOM evolved, increasing the relative importance of nonvaccine serotypes of *S. pneumoniae* (NV-Sp) and emergence of NTHi as the most common otopathogen in children failing initial therapy.[11–13] Molecular strategies demonstrate an increased identification of NTHi in previous culture-negative cases of recurrent otitis media and when tympanostomy tubes are inserted.[14]

Streptococcus pneumoniae

Pneumococcus is recovered from 30% to 50% of children with AOM.[15–19] Before the US introduction of PCV7, 70% of episodes of pneumococcal AOM were caused by seven serotypes (Fig. 29.2).[20] After universal implementation of PCV7 and PCV13, a shift occurred in serotypes recovered from middle ear cultures of children with AOM, with a progressive decline in V-Sp 19 A cases between 2011 and 2013 and frequent recovery of NV-Sp serotypes, including 6C, 11, 15 A, 15B/C, 21, 23B, and 35.[21,22]

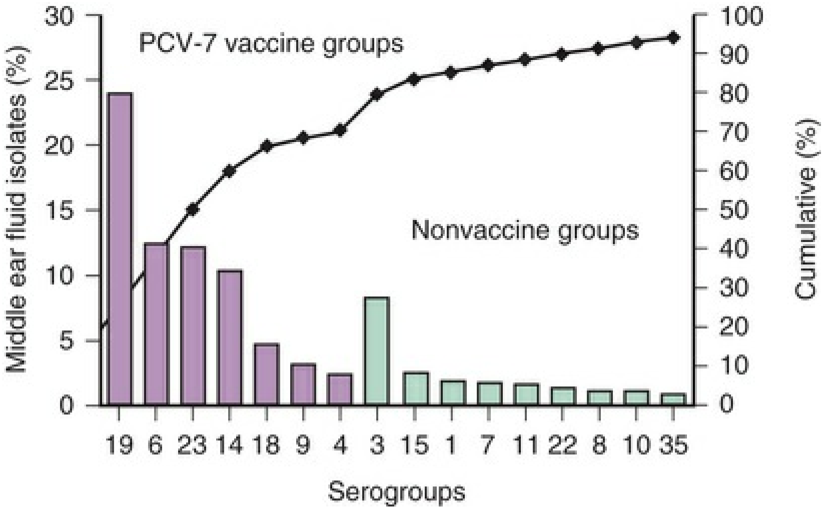


FIGURE 29.2 Serogroups of *Streptococcus pneumoniae* that caused acute otitis media in North American children in 2000. PCV-7, 7-valent pneumococcal conjugate vaccine. (Modified from Hausdorff WP, Bryant J, Kloek C, et al. The contribution of specific pneumococcal serogroups to different disease manifestations: implications for conjugate vaccine formulation and use. Part II. Clin Infect Dis 2000;30:122–140.)

From 1985 through 1999, increasing penicillin and multidrug resistance emerged among isolates of *S. pneumoniae*. Resistance was most common among five to seven of the PCV7 serotypes.[23] Implementation of PCV7 was associated initially with a decrease in penicillin and multidrug resistance, but it was followed by increasing penicillin resistance due to replacement NV-Sp.[2,24] After the PCV13 introduction, colonization and infection due to penicillin-nonsusceptible and multidrug-resistant *S. pneumoniae,* primarily serotype 19A, declined dramatically to current levels of 20% or less. Currently, 30% of *S. pneumoniae* isolates remain resistant to azithromycin, but few isolates have resistance to ceftriaxone or high-level resistance to penicillin.

Haemophilus influenzae

NTHi causes a substantial proportion of cases of AOM in children.[25] A well-recognized clinical syndrome, otitis–conjunctivitis, is associated with recovery of NTHi from the middle ear and conjunctiva.[26] Several investigators have reported an increased proportion of disease due to NTHi among immunized children who have persistent or recurrent disease after initial treatment.[12,13] Most isolates of NTHi produce β-lactamase and are amoxicillin resistant. In Japan and France, isolates of NTHi with high-level resistance to amoxicillin due to alterations in the penicillin-binding proteins have been recovered from children with AOM,[27] but they remain uncommon in the United States.[28]

In the last decade, molecular techniques (PCR amplification) have provided insights into the microbiology of recurrent AOM and persistent otitis media with effusion (OME). Middle ear biofilm formation, most commonly associated with NTHi, is frequent and often recalcitrant to antimicrobial treatment.[29]

Moraxella catarrhalis

M. catarrhalis is a bona fide pathogen in AOM. It is isolated from middle ear culture samples from children with AOM and prompts a humoral immune response.[30] The organism appears to be more prevalent in certain geographic areas and in the first year of life.

Group A *Streptococcus*

Otitis media due to GAS was common in the preantibiotic era. Currently, GAS most often is recovered from school-aged children with AOM. A greater relative importance of GAS is reported in eastern European children than in US children.

Staphylococcus aureus and *Staphylococcus epidermidis*

The role of *Staphylococcus aureus* as a pathogen in AOM remains controversial. In Japan and South Africa, *S. aureus* is reported as a primary pathogen of AOM in children and is recoverable from tympanocentesis fluid.[31] *S. aureus* is recovered from less than 3% of middle ear cultures from US children with AOM and an intact tympanic membrane. Methicillin-susceptible *S. aureus* (MSSA) and community-associated methicillin-resistant *S. aureus* (CA-MRSA) are identified pathogens in children with acute otorrhea associated with a tympanostomy tube.[32,33]

Epidemiology

Otitis media is virtually universal in childhood. Studies of the age-specific incidence of AOM in Denmark between 1996 and 2003 reported that 16% of children had first episodes between 0 and 6 months of age, 44% between 7 and 18 months, and 40% between 19 months and 7 years. Before 7 years of age, 40% had 4 or more episodes.[34]

Risk factors for AOM are young age, exposure to young children (i.e., group childcare attendance or siblings in household), and a positive family history.[35,36] Studies evaluating features such as race, breastfeeding, use of a pacifier, and exposure to cigarette smoke have identified associations with AOM less consistently.[37–40]

Recognition of the otitis-prone child has been important in the development of strategies for reducing the burden of AOM and OME. Onset of disease in the first few months of life is a sentinel event that can result from risk factors and can create enhanced susceptibility to later events. Children who had their first episode before 6 months of age are most likely to develop recurrent AOM. In the past decade, several studies of insurance claims document a decline in the number of AOM-related visits in the US, Canada, and United Kingdom.[41–43] Large studies of US children younger than 7 years of age show a downward trend in otitis media visit rates from 2004 to 2011, with a significant drop that coincided with the introduction of PCV13 in 2010.[41] Other factors that likely contributed are more stringent diagnostic criteria, expanded use of influenza vaccine, and adoption of initial observation for some children.

Studies by Grijalva and colleagues[42] and de Wals and coworkers[43] concluded that the decline in AOM preceded and likely was accelerated by the introduction of PCV7.[42,43] Although clinical trials demonstrated only a modest reduction in AOM episodes, some investigators have hypothesized that substantial reduction in tympanostomy tube insertion is related to prevention of early pneumococcal otitis media and its attendant events.

Management

Many issues influence strategies for the treatment of AOM, including the natural history of AOM, relevance of clinical versus microbiologic end points, antibiotic choices according to current susceptibility patterns of otopathogens, published guidelines for management, and the relative risk of observation versus treatment.

Natural History

In the preantibiotic era, mastoiditis was a common complication of AOM. Antimicrobial therapy for the treatment of AOM has resulted in a dramatic decline in its incidence. Similarly, in certain populations, such as Alaskan Eskimos, chronic otorrhea occurred in about 30% of children before the routine use of antimicrobial therapy.[44] In 1999, Baxter[45] reported a substantial decline in chronic otorrhea cases over a 30-year period that was associated with the introduction of routine antimicrobial therapy for the treatment of AOM. During the same period, socioeconomic conditions also improved, blurring the specific contribution of medical management.

An episode of AOM usually resolves in most children with or without antimicrobial therapy. Antibiotic treatment does not benefit the 20% to 30% of episodes of middle ear disease with negative culture results, and some children with bacterial AOM clear the pathogen spontaneously.[46]

Therapeutic trials that include a placebo group consistently report excess failure rates for children who receive only symptomatic treatment; however, the significance of these differences is debated. Little and coworkers[47] compared the outcomes of children with AOM initially treated with amoxicillin with those of children given a prescription to be filled only if symptoms persisted for 72 hours. Children initially treated with antibiotics improved more quickly.

McCormick and colleagues[48] evaluated the strategy of watchful waiting for children with perceived mild disease as defined by a structured assessment. Children assigned to the delayed treatment group had increased treatment failures and persistent symptoms (Table 29.2). More frequent, mild adverse events and the emergence of multidrug-resistant isolates of *S. pneumoniae* in the nasopharynx occurred in the early-treatment group. Evaluating outcomes within the first 3 to 5 days of treatment provides the best evidence for more rapid resolution in antibiotic-treated compared with placebo-treated cohorts and differences between antibiotic regimens.[49,50] Effective antimicrobial therapy sterilizes the middle ear, resulting in a more rapid resolution of clinical signs (i.e., bulging and erythema) and symptoms (i.e., fever, earache, and irritability).

TABLE 29.2

Clinical Outcomes by Treatment Assignment and Age

Treatment Assignment by Age Cohort	Failure (Day 0–12)		Recurrence (Day 13–33)		Cure	
	No.	%	No.	%	No.	%
<2 YEARS						
Antibiotic immediately	4	6	11	17	50	77
Watchful waiting	12	24	10	20	28	56
Total	16	14	21	18	78	68
>2 YEARS						
Antibiotic immediately	1	2	9	21	34	77
Watchful waiting	9	18	3	6	38	76
Total	10	14	12	16	72	76

From McCormick DP, Chonmaitree T, Pittman C, et al. Nonsevere acute otitis media: a clinical trial comparing outcomes of watchful waiting versus immediate antibiotic treatment. Pediatrics 2005;115:1455–1465.

Two clinical trials described the magnitude of the benefit of antibiotic treatment in children residing in industrialized countries[51,52] One study reported a substantial benefit for amoxicillin-clavulanate compared with placebo for resolution of fever, irritability, decreased activity, and poor appetite.[52] In the other, treatment with amoxicillin-clavulanate was associated with a lower symptom score over the first 7 days.[51] If the outcome of recurrence within 30 days is measured, small but statistically significant differences are reported between children given effective antimicrobial therapy and those given placebo or ineffective therapy.[53]

Between 30% and 50% of children, especially younger children, have persistent OME 30 days after an episode of AOM, long after resolution of the acute signs and symptoms.[54] In a longitudinal study, 40% of children with AOM had OME at 1 month, 20% at 2 months, and 10% at 3 months.[55] OME is associated with conductive hearing loss of up to 50 decibels (dB) during fluid persistence.[56]

Pharmacodynamic Principles of Antimicrobial Selection

In 1992, the Infectious Disease Society of America established guidelines for evaluation of new agents for treatment of AOM,[57] requiring both clinical and microbiologic studies and outcome measures 3 to 5 days after initiation of antimicrobial therapy. Guidelines are consistent with the principles established by Carlin and colleagues[58] and confirmed by Dagan and associates[59] that the middle ear concentration of an antibiotic has a high correlation with clinical success (Table 29.3)

TABLE 29.3

Correlation Between Microbiologic Outcome at Day 4 or 5 and Clinical Outcomes of Patients With Acute Otitis Media

Clinical Outcome	Culture Negative at Day 4 or 5		Culture Positive at Day 4 or 5	
	No.	%	No.	%
Success	236	93	25	62.5
Failure	17	7	15	37.5

Modified from Carlin SA, Marchant CD, Shurin PA, et al. Host factors and early therapeutic response in acute otitis media. J Pediatr 1991;118:178–183.

The selection of antimicrobial therapy should be based on pharmacodynamic principles and results of clinical trials using microbiologic end points. β-Lactam agents and trimethoprim-sulfamethoxazole (TMP-SMX) depend on the time that the drug concentration is above the minimal inhibitory concentration (MIC) for efficacy.[60] Efficacy (i.e., sterilization of middle-ear fluid) of β-lactam agents is predicted when the drug concentration in middle ear fluid exceeds the MIC for about 40% of the dosing interval.[61] For azalides (e.g., azithromycin) and fluoroquinolones, ratios of the area under the antibiotic concentration curve per 24 hours (AUC_{24}) to MIC or the peak concentration to MIC are relevant, and for azithromycin, an AUC_{24} to MIC ratio of 25 predicts efficacy (for pneumococcus).[62]

Although these principles are well established, controversy persists regarding whether extracellular or intracellular concentrations of antibiotics are necessary. For β-lactam agents, there is no enhanced intracellular accumulation. However, for azalides and ketolides, intracellular concentrations of drug exceed extracellular (serum) concentrations up to 100-fold. Results from animal models and clinical trials suggest that extracellular concentrations are the critical correlate.[63]

The acceptance of these principles led the Clinical and Laboratory Standards Institute (CLSI) to identify specific criteria (i.e., breakpoints) for susceptibility or resistance relative to sites of infection. Table 29.4 summarizes the CLSI-specific breakpoints and those derived from pharmacodynamic analysis for *S. pneumoniae* and NTHi.[64]

TABLE 29.4

CLSI and Pharmacodynamic Breakpoints for Selected Antimicrobial Agents and Otopathogens

Antibiotic	CLSI Breakpoints[a] (μg/mL)		Pharmacodynamic Breakpoints[a] (μg/mL)
	Streptococcus Pneumoniae	*Haemophilus Influenzae*	
Amoxicillin	2	4	2
Amoxicillin-clavulanate	2	4	2
Cefuroxime	1	4	1
Cefprozil	2	8	1
Cefixime	0.5	1	1
Cefaclor	1	8	0.5
Loracarbef	2	8	0.5
Azithromycin	0.5	4	0.12
Clarithromycin	0.25	8	0.25

[a] Breakpoint is a concentration used in the interpretation of results of susceptibility testing to define bacterial isolates as susceptible, intermediate, or resistant.

CLSI, Clinical and Laboratory Standards Institute.

Data from National Committee for Clinical Laboratory Standards (NCCLS). Performance Standards for Antimicrobial Susceptibility Testing. Tenth Informational Supplement. Wayne, PA: NCCLS; 2000.

In most cases of AOM, the specific pathogen is unknown, and presumptive therapy is based on the likely pathogens and their in vitro susceptibility. The proportion of isolates of NTHi producing β-lactamase is approximately 40%,[65] and penicillin-nonsusceptible isolates due to altered penicillin-binding proteins is approximately 20%.[66–68] CLSI breakpoints for *S. pneumoniae*, redefining resistant as isolates with a penicillin MIC of 8 μg/mL or greater, are more consistent with pharmacokinetic or pharmacodynamic principles.

Resistance to macrolides and azalides is mediated by an efflux pump mechanism that decreases intracellular accumulation of antibiotic or by a mutation in ribosomal methylase that affects binding between the drug and target site, or both.[69,70] Susceptibility of nasopharyngeal isolates of *S. pneumoniae* in Massachusetts children from 2008 and 2009 and AOM isolates in infants in Rochester, NY, in 2011 and 2012 based on the 2000 CLSI guidelines are shown in Table 29.5 and Table 29.6, respectively. Data from France suggest that the proportion of macrolide-resistant and penicillin-nonsusceptible pneumococcal carriage has declined in the PCV13 era, whereas that of amoxicillin-resistant NTHi remains unchanged.[71] Risk factors for penicillin-nonsusceptible *S. pneumoniae* are age younger than 2 years, recent treatment with antibiotics, season (i.e., late winter to early spring), and attendance in group childcare.[72,73] For most isolates with a penicillin MIC of 2 to 8 µg/mL, a 10-day course of high-dose (90 mg/kg/day) amoxicillin or a three-dose regimen of ceftriaxone (50 mg/kg/day) has proved effective for AOM.[53,74]

TABLE 29.5

Proportion of Antibiotic Resistance Among 2008–2009 Pneumococcal Isolates From Children Younger Than 7 Years in Massachusetts

Antibiotic[a]	Total Isolates (%) (*N* = 290)
PNSP	98 (34)
PCN-I[b]	64 (22)
PCN-R[c]	34 (12)
Erythromycin-NS	83 (29)
Clindamycin-NS	29 (10)
Trimethoprim-sulfamethoxazole-NS	58 (20)
Ceftriaxone-NS	30 (10)
MDR1[d]	81 (28)
MDR2[e]	55 (19)

[a] The following breakpoints were used for PNSP (>0.06), erythromycin-NS (>0.25), clindamycin-NS (>0.5), trimethoprim-sulfamethoxazole-NS, (>0.5), and ceftriaxone-NS (>1.0).

[b] Based on the pre-2008 breakpoint for penicillin intermediate susceptibility (MIC 0.06–1.0 mg/L).

[c] Based on the pre-2008 breakpoint for penicillin resistance (MIC ≥2.0 mg/L).

[d] MDR1 refers to multidrug resistance defined as nonsusceptibility to penicillin plus one other antibiotic class.

[e] MDR2 refers to multidrug resistance defined as nonsusceptibility to three or more classes of antibiotics.

I, Intermediate susceptibility; MIC, minimal inhibitory concentration; MDR, multidrug resistance; NS, nonsusceptible; PCN, penicillin; PNSP, penicillin-nonsusceptible *Streptococcus pneumoniae*; R, resistant.

Modified from Wroe FC, Lee GM, Finkelstein JA, et al. Pneumococcal carriage and antibiotic resistance in young children before 13-valent conjugate vaccine. Pediatr Infect Dis 2012;31:249–254.

TABLE 29.6

Bacteria Causing Acute Otitis Media in Infants in Rochester, New York, During the 2011–2012 Respiratory Season

Pathogen	Proportion of Total Bacterial Pathogens	Proportion That Were Amoxicillin Resistant
Streptococcus pneumoniae	12%	20%
Haemophilus influenzae	56%	50%
Moraxella catarrhalis	22%	100%

Modified from Pichichero ME. Otitis media. *Pediatr Clin North Am.* 2013;60:39.

Pharmacokinetic or pharmacodynamic data and anecdotal evidence support the efficacy of clindamycin for susceptible isolates. Animal studies support the efficacy of linezolid against drug-resistant *S. pneumoniae*.[75] Linezolid, however, has no activity against NTHi.

Defining Clinical Failure, Relapse, and Recurrence

Review of seven clinical trials comparing antibiotic and placebo treatments for AOM identified *treatment failure* (i.e., persistence of symptoms) in 15% of cases at 2 to 3 days, in 10% at 6 to 7 days, and in 9% at 7 to 14 days.[49] The failure of AOM to respond to initial antimicrobial therapy is related to the severity of the initial symptoms and the age of the patient.[59,76] Kaleida and associates[76] observed after 24 hours of therapy that 12% of severely symptomatic patients younger than 2 years but only 4.1% of children 2 years or older with similar severity of symptoms showed no improvement with therapy. Among children with nonsevere AOM, only 6% who were younger than 2 years and less than 1% of those older than 2 years of age had no improvement.

In studies performed before PCV7 became available or in countries where PCV7 immunization is not universal, β-lactamase–positive NTHi was isolated from tympanocentesis specimens in 50% of cases and nonsusceptible *S. pneumoniae* in 25% of cases of high-dose amoxicillin treatment failure.[77] A study conducted during the PCV7 era reported high rates of treatment failure among children younger than 2 years of age (Fig. 29.3) and relatively comparable rates for antimicrobial regimens.[78]

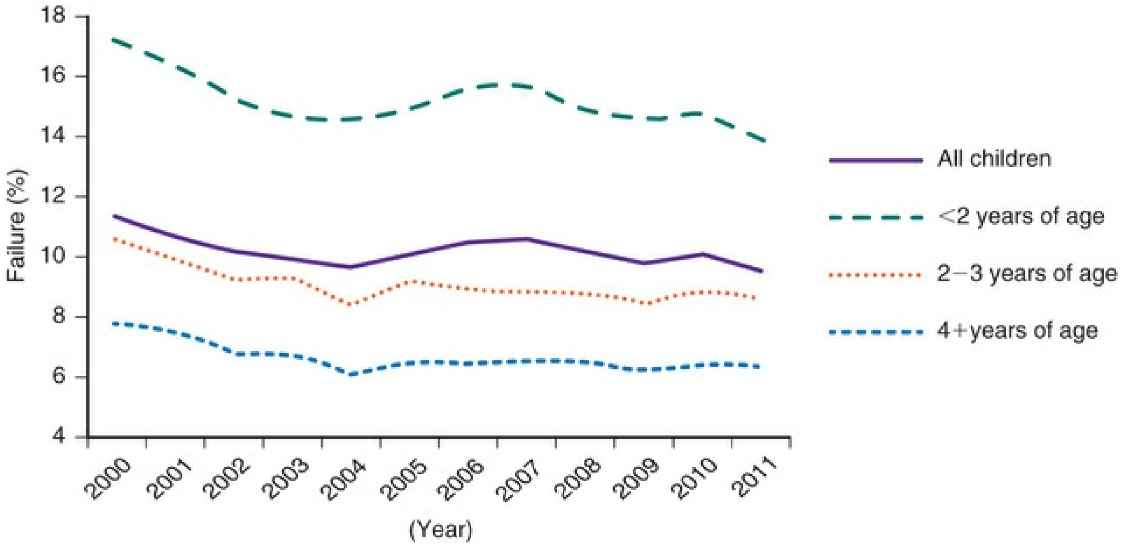

FIGURE 29.3 Rates of antibiotic failure among children with an acute otitis media diagnosis are shown for four age categories from 2000 to 2011. (From McGrath LI, Becker-Dreps S, Pate V, Brookhart MA. Trends in antibiotic treatment of acute otitis media and treatment failure in children, 2000−2011. PLoS One 2013;8:e812107.)

Antimicrobial treatment for these children must include agents active against pneumococcus and NTHi organisms. Ceftriaxone, high-dose amoxicillin-clavulanate, high-dose amoxicillin in combination with cefixime or ceftibuten, and standard-dose amoxicillin in combination with amoxicillin-clavulanate are appropriate. Studies of gatifloxacin and levofloxacin demonstrate in vitro activity against all NTHi and more than 95% *S. pneumoniae.* Clinical trials demonstrate rapid sterilization and clinical resolution of middle ear infection due to either pathogen.[79,80] However, fluoroquinolones are not licensed for use in children for the treatment of AOM.

Universal use of PCV13 has reduced circulation of multidrug-resistant pneumococcus in the community and recovery of such isolates (especially serotype 19A) from children with AOM and mastoiditis.[81] Vancomycin or levofloxacin plus tympanostomy tube insertion or linezolid have provided successful treatment for AOM multidrug-resistant serotype 19A.[82,83]

Relapse and *recurrence* are defined as occurrence of AOM after an initial symptomatic response to antibiotics during treatment or within a defined period after completion of therapy. Differentiating relapse from recurrence requires defining the microbiology of both episodes. Leibovitz and colleagues demonstrated that most relapses that occurred within 1 month after completion of antibiotic therapy were caused by new pathogens or different serotypes of the same pathogen.[77] Other studies showed that ceftriaxone or other β-lactam therapy for AOM eliminated susceptible isolates of *S. pneumoniae* from the nasopharynx but had little effect on resistant strains.[84,85] Beginning as early as 3 to 4 days into the course of treatment, new strains of antibiotic-resistant *S. pneumoniae* are acquired.[86] Recurrent episodes of AOM are more likely to be caused by resistant pathogens.[47]

Fig. 29.4 demonstrates that the likelihood of recovering a penicillin-nonsusceptible pneumococcus correlates with time since last receipt of antibiotics.[87] The data support the recommendation from the American Academy of Pediatrics (AAP) that treatment of recurrent episodes within 30 days of a prior event may necessitate use of antibiotic agents (e.g., ceftriaxone, high-dose amoxicillin-clavulanate) that target resistant otopathogens.[88]

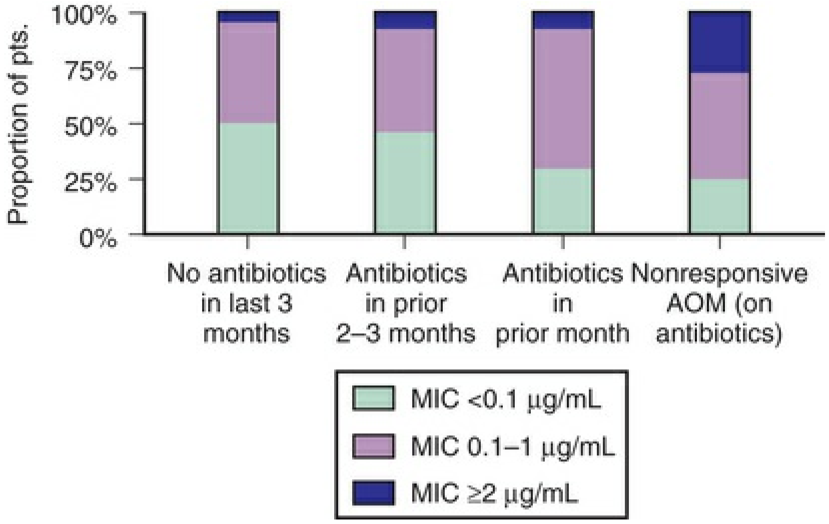

FIGURE 29.4 Correlation between recent antibiotic therapy and likelihood of drug-resistant *Streptococcus pneumoniae* in patients *(pts.)* with acute otitis media *(AOM)*. MIC, Minimum inhibitory concentration. (Modified from Jacobs MR. Increasing antibiotic resistance among otitis media pathogens and their susceptibility to oral agents based pharmacodynamic parameters. Paediatr Infect Dis J 2000;19:S47–S55.)

American Academy of Pediatrics Guidelines for the Diagnosis and Treatment of Acute Otitis Media

The AAP guidelines were published in 2004 and revised in 2013. They define middle ear effusion as detected by physical examination or tympanometry plus an opaque tympanic membrane (i.e., evidence of inflammation) as the critical criterion for the diagnosis of AOM.[88,89] Classification as AOM also requires recent onset of signs and symptoms of acute inflammation such as earache, ear tugging, or a bulging tympanic membrane. The 2013 AAP and American Academy of Family Physicians (AAFP) guideline recommends immediate antibiotic treatment for children younger than 6 months of age, children with severe signs or symptoms (i.e., moderate or severe ear pain, ear pain for ≥48 hours, or temperature ≥39°C [102.2°F]), and children older than 24 months of age with bilateral AOM.[88]

The 2013 AAP/AAFP guideline recommends immediate treatment or observation (with pain control) for children between 6 and 24 months of age with unilateral, nonsevere AOM and for children 24 months or older with unilateral or bilateral, nonsevere AOM. Additional analysis shows a high rate of treatment failure among children younger than 24 months with unilateral, nonsevere AOM,[89] and the observational approach remains controversial.

Amoxicillin remains the first-line therapy for children with AOM who are treated with antibiotics and at low-risk for amoxicillin resistance (Table 29.7).[87,88] Among β-lactam antibiotics, only oral high-dose amoxicillin or intramuscular ceftriaxone achieves middle ear concentrations that fulfill pharmacokinetic or pharmacodynamic requirements for penicillin-nonsusceptible *S. pneumoniae* and β-lactamase–nonproducing NTHi. Cefuroxime axetil, cefprozil, and cefpodoxime are alternatives to high-dose amoxicillin, but each only achieves a sufficient middle ear concentration to be effective against less than 50% of penicillin-nonsusceptible *S. pneumoniae*. Cefprozil has limited activity against NTHi.[90]

TABLE 29.7

Recommendations for Initial or Delayed Treatment of Acute Otitis Media and After Initial Treatment Failure

Initial Immediate or Delayed Antibiotic Treatment		Antibiotic Treatment After 48–72 hr of Failure of Initial Antibiotic Treatment	
Recommended First-Line Treatment	**Alternative Treatment (for Penicillin Allergy)**	**Recommended First-Line Treatment**	**Alternative Treatment**
Amoxicillin (80–90 mg/kg per day in 2 divided doses) *or* Amoxicillin-clavulanate[a] (90 mg/kg/day of amoxicillin with 6.4 mg/kg/day of clavulanate [amoxicillin to clavulanate ratio of 14:1] in 2 divided doses)	Cefdinir (14 mg/kg/day in 1 or 2 doses) *or* Cefuroxime (30 mg/kg/day in 2 divided doses) *or* Cefpodoxime (10 mg/kg/day in 2 divided doses) *or* Ceftriaxone (50 mg/day IM or IV for 1	Amoxicillin-clavulante[a] (90 mg/kg/day of amoxicillin with 6.4 mg/kg/day of clavulanate in 2 divided doses) *or* Ceftriaxone (50 mg/day IM or IV for 3 days)	Ceftriaxone (50 mg/day IM or IV for 3 days) *or* Clindamycin (30–40 mg/kg/day in 3 divided doses) with or without a third-generation cephalosporin After failure of a second antibiotic • Clindamycin (30–40 mg/kg/day in 3 divided doses) plus a third-generation cephalosporin • Consider

	or 3 days)		tympanocentesis and a subspecialty consultation[b]

[a] May be considered in patients who have received amoxicillin in the previous 30 days or who have the otitis conjunctivitis syndrome.

[b] Perform tympanocentesis or drainage if skilled in the procedure, or seek a consultation with an otolaryngologist for tympanocentesis or drainage. If the tympanocentesis reveals multidrug-resistant bacteria, seek an infectious diseases specialist consultation.

IM, intramuscular; IV, intravenous

Modified from Lieberthal AS, Coroll AE, Chonmaitree T, et al. The diagnosis and management of acute otitis media. Pediatrics 2013;131:e964–e969

Macrolide efficacy at the recommended dosage is limited to disease due to susceptible *S. pneumoniae*. Extracellular middle ear fluid concentrations of macrolides are below the MIC for almost all NTHi and *S. pneumoniae* isolates with efflux or a ribosomal mechanism of resistance. Amoxicillin is ineffective against β-lactamase–producing isolates of NTHi. Amoxicillin-clavulanate resists destruction by β-lactamase and effectively eradicates middle ear infection caused by virtually all NTHi. Isolates of NTHi with altered penicillin-binding proteins (i.e., β-lactamase negative, ampicillin-resistant strains) are common in Japan and have been reported rarely in the US,[91] as have isolates with both altered penicillin-binding proteins and β-lactamase production. These isolates can have MICs for amoxicillin that are at the breakpoint for effective eradication even with the recommended high-dose strategy. Amoxicillin-clavulanate is preferred as first-line therapy when children treated for AOM have an increased risk of β-lactam resistance, including having received a β-lactam antibiotic in the previous 30 days, having concomitant purulent conjunctivitis, or having a history of recurrent AOM; NTHi is predominant in the latter two settings.

Initial therapy for the child with a type I (hypersensitivity) allergic reaction to penicillin (i.e., urticaria, laryngeal spasm, wheezing, or anaphylaxis) remains challenging. The choice of alternatives to β-lactams is limited by the substantial prevalence of resistance. Macrolides and lincosamides lack activity against most *H. influenzae* isolates, and approximately one third of pneumococcal isolates are resistant to macrolides. Resistance to TMP-SMX among *S. pneumoniae* and NTHi isolates also is substantial.[87]

Acknowledging potential limitations, the AAP guidelines recommend these agents as the best alternatives. Patients with other types of allergic reactions can be treated with cefdinir, cefpodoxime, cefuroxime, or intramuscular ceftriaxone.

For the allergic child with severe AOM, a combination of agents such as clindamycin and sulfisoxazole may be effective. Unlike macrolides, clindamycin can be effective against isolates of *S. pneumoniae* with the efflux mechanism of resistance and therefore maintains activity against approximately 80% to 90% of *S. pneumoniae* isolates in the US. However, the proportion of isolates of *S. pneumoniae* with ribosomal mechanisms of resistance is increasing, and local or community antimicrobial susceptibility patterns provide the best prediction for the efficacy of clindamycin.[92]

Oral rather than topical therapy is preferred for children with acute otorrhea without a tympanostomy tube. Although topical therapy with a fluoroquinolone otic drop (i.e., ofloxacin or ciprofloxacin) is equivalent to oral therapy for the treatment of otorrhea in children with tympanostomy tubes or chronic suppurative otitis media, topical therapy has not been studied in children with AOM and acute perforation.[88]

The AAP guidelines emphasize that watchful waiting includes providing analgesia for children suffering from AOM. Limited data suggest that ibuprofen or acetaminophen is effective.[93] Topical benzocaine, procaine, or lidocaine (if available) preparations are an alternative for children ≥2 years of age but should not be used in children with a tympanic membrane perforation. Topical benzocaine is avoided in children younger than 2 years of age because of the risk of methemoglobinemia. For children with severe pain, myringotomy is an effective method to attain relief.

Evaluation of the Child With Recurrent Otitis Media

In clinical practice, most children with recurrent otitis media do not have a quantifiable immunologic abnormality.[94,95] When an immune defect is detected, the abnormality usually is limited to IgG subclasses or an IgA deficiency.[94,96] These disorders often are maturational, and repeated testing at 4 years of age or later can show resolution. For children with recurrent serious infections in addition to recurrent otitis media, more serious immunologic defects must be considered.

Recurrent AOM is common in children with Human immunodeficiency virus (HIV) infection.[97–100] Additional signs of immunodeficiency, such as recurrent thrush, lymphadenopathy, hepatomegaly or splenomegaly, failure to thrive, and chronic diarrhea, usually are present, although recurrent AOM can be the presenting or dominant feature early in life.[101] In 60 episodes of AOM in HIV-infected children, *S. pneumoniae,* NTHi, and GAS were recovered from the middle ear in 56% of cases, a proportion similar to that seen in immunocompetent children. *S. aureus* was identified in HIV-infected children with severe immune compromise.

Immunologic evaluation of the child whose recurrent infections are limited to AOM and who does not have failure to thrive, chronic diarrhea, lymphadenopathy, or organomegaly is unlikely to reveal a serious immune deficiency. Kaur and colleagues[102] and Sharma and colleagues[103,104] studied otitis-prone children. They found that reduced memory $CD4^+$ T lymphocyte generation in the circulation of young children may contribute to the condition.[102–104]

Prevention of Recurrent Acute Otitis Media

Decreasing the morbidity of otitis media has implications for decreasing antimicrobial use and the associated emergence of resistance, reducing healthcare costs and surgical procedures, preventing the language and cognitive delays that occur in some children with recurrent AOM, and preventing prolonged conductive hearing loss. In the pre-PCV7 era, Paradise and colleagues observed that approximately 45% of urban children in the first year of life and 30% in the second year spent more than 3 months of each year with middle ear effusion; 10% of children spent more than 50% of each year with middle-ear effusion.[105]

Prevention of recurrent bacterial AOM can be achieved by preventing nasopharyngeal colonization with otopathogens, preventing viral respiratory tract infection, and providing specific antibacterial immunity. Several interventions, including breastfeeding, avoidance of supine bottle feeding and bottle propping, limiting pacifier use, and frequent hand hygiene can have a modest benefit for prevention of respiratory tract infection and AOM. Specific interventions such as insertion of tympanostomy tubes do not reduce the frequency of acute episodes substantially, but they shorten the duration of middle ear effusion.[106]

Antimicrobial prophylaxis lowers the frequency of colonization with respiratory otopathogens and decreases AOM episodes.[107] The greatest benefit occurs for children at highest risk for recurrent AOM (i.e., 6 to 24 months old) and for otitis-prone children who have multiple episodes per year and for whom the problem does not abate with increasing age.

Chemoprophylaxis

Chemoprophylaxis offers only short-term benefits. Most otitis-prone children continue to have recurrent episodes when prophylaxis is discontinued until immunologic and eustachian tube function have matured.[107] Use of a five-carbon sugar alcohol, xylitol, reduced episodes of AOM in group childcare attendees in Finland (3.03 vs. 2.01 episodes per child-year).[108,109] A US study of xylitol administered as a viscous solution at a dose of 5 g three times per day to otitis-prone children failed to reduce the incidence of clinically diagnosed AOM.[110]

Vaccination

Viral respiratory tract illness is a cofactor in the pathogenesis of AOM. Influenza vaccine has been associated with a reduction in AOM episodes, in febrile AOM, and in myringotomy and insertion of tympanostomy tubes over a winter season.[111] A Cochrane review concluded that annual influenza vaccination solely for its modest effect on reducing AOM and attendant antibiotic use was not justified.

Three pneumococcal conjugate vaccines (i.e., PCV_{CRM}, PCV_{OMP}, and PHiD-CV) administered at 2, 4, and 6 months with a booster at 12 to 15 months of age reduced AOM due to vaccine serotypes of *S. pneumoniae* by approximately 60% (Table 29.8).[112–114] However, the overall reduction of 6% to 10% in episodes of AOM was modest in two clinical trials of PCV7.

TABLE 29.8

Efficacy of 7-Valent Pneumococcal Conjugate Vaccine (PCV7) for the Prevention of Pneumococcal Otitis Media

Cross-Reactive Serotypes (6A, 9N, 18B, 19A, 23A)	No. of Episodes		Difference (%)
	PCV7	Control	
All pneumococcal episodes	271	414	↓34
All serotypes included in the vaccine	107	250	↓57
Vaccine serogroups	41	84	↓51
Nonvaccine serogroups	125	95	↑33

Data from Eskola J, Kilpi T, Palmu A, et al. Efficacy of a pneumococcal conjugate vaccine against otitis media. N Engl J Med 2001;344:403–409.

Initial results with an 11-valent pneumococcal polysaccharide vaccine conjugated to protein D from *H. influenzae* (PHiD-CV) demonstrated that protection against AOM could be extended to include NTHi and vaccine serotypes of *S. pneumoniae*.[114] PHiD-CV has been reformulated as a 10-valent pneumococcal vaccine with 8 of the polysaccharides conjugated to protein D. The efficacy of PHiD-CV was 19% (95% confidence interval [CI], 4%–31%) against first episodes of clinically confirmed AOM and 70% (95% CI, 30%–87%) against bacteriologically confirmed AOM caused by vaccine serotypes. In observational studies in Goiânia, Brazil, a 45% reduction in outpatient visits for otitis in 2011–2013 was reported among children younger than 24 months compared with rates before PHiD-CV introduction (2008–2010).[114]

Follow-up studies of cohorts of the original clinical trials of infant immunization with PCV7 in California and Finland identified significant reductions in tympanostomy tube insertions in immunized children.[115,116] Studies of PCV7 immunization in children who already suffer with frequent ROM have failed to demonstrate a significant reduction in episodes.[108] PCV7 postmarketing studies confirmed an increase in AOM due to NV-Sp. and NTHi.[13] Post-PCV13 studies showed a further reduction in healthcare visits for AOM and insertion of tympanostomy tubes.[41] There was concurrently an increased rate of tympanic membrane perforation or otorrhea but substantial declines in mastoiditis.[41] Substantial reduction in pneumococcal AOM with near elimination of cases due to PCV13 serotypes was documented after PCV7/PCV13 introduction in Southern Israel.[117] These studies are unable to delineate a reduction of AOM due to the direct and indirect effects of PCVs from the changes in diagnostic criteria and management of AOM that have occurred over the decade.

Complications of Acute Otitis Media

Perforation of the tympanic membrane is the most common complication of AOM and is observed most frequently in young children. Studies comparing children with AOM managed with antibiotics compared with initial observation demonstrate excess cases of perforation in the observation group.[51,52] AOM in certain ethnic groups, such as Alaskan Eskimos and Native Americans, is associated with a higher incidence of spontaneous perforation. The microbiology of AOM with acute perforation demonstrates a higher proportion of cases due to GAS and *S. aureus*.[33]

The typical natural history of AOM with perforation is complete resolution with healing of the tympanic membrane. A few patients have persistent dry perforation or chronic suppurative otitis media persisting for 6 to 12 weeks. *S. pneumoniae* and NTHi are the most common pathogens in infants and toddlers, whereas *S. aureus* and *Pseudomonas aeruginosa* are frequent pathogens in older children with tympanostomy tubes and during the summer months.[118]

Amoxicillin usually is effective for the treatment of acute otorrhea through a tympanostomy tube, and compared with placebo, it results in rapid clearing of bacterial pathogens and a shortened duration of otorrhea.[119] An alternative to oral antimicrobial therapy is topical otic suspensions of ofloxacin or ciprofloxacin.[120,121] When CA-MRSA is recovered, oral TMP-SMX or topical fluoroquinolone preparations can have transient benefit, but drainage often recurs.[122,123]

Facial palsy is an uncommon complication of AOM.[124] Facial weakness and earache are predominant symptoms. Antibiotic therapy and myringotomy (with or without tube insertion) usually are sufficient to achieve complete resolution.

Mastoiditis, although decreased dramatically since the routine antibiotic treatment of AOM, remains the most common suppurative complication.[125] *S. pneumoniae,* GAS, and NTHi are the most common pathogens in cases of acute mastoiditis but *P. aeruginosa* was found in 29% and *S. epidermidis* in 31% of cases in one large series.[125] These pathogens should be suspected when otorrhea precedes development of acute mastoiditis.

Labyrinthitis develops when AOM spreads through the round window into the cochlear space. The process can be suppurative or serous (due to bacterial toxins). The onset of labyrinthitis often is sudden, with characteristic vertigo and hearing loss. Acute surgical intervention (i.e., myringotomy with tube insertion) plus antimicrobial therapy provide optimal therapy. Additional rare complications of AOM are brain abscess, epidural abscess, and otic hydrocephalus, which can result from transverse, lateral, or sigmoid sinus thrombosis.

Otitis Media With Effusion

OME is a relatively asymptomatic middle ear effusion that often is associated with conductive hearing loss and can persist for months. The pathogenesis most often reflects a postinfectious event that results from local cytokines and other inflammatory mediators. Biofilm formation and persistence by bacterial otopathogens, individually or in combination, have primary pathogenetic importance and are responsible for ongoing inflammation that leads to persistence of the middle ear effusion.[126–128]

In most children, OME resolves without intervention within a few months.[129] When OME persists beyond this period and there is a substantial conductive hearing loss (>20 dB), intervention with tympanostomy tubes and adenoidectomy may be considered. Consequences of tube placement can include recurrent otorrhea, persistent perforation, development of granulation tissue, chronic otitis media, and cholesteatoma.[130] Repeated insertions of tympanostomy tubes also have been associated with mild hearing loss, including a sensorineural component.[131]

Guidelines from the AAP and American Academy of Otolaryngology[129] and their restatement in the 2012 American Academy of Otolaryngology–Head and Neck Surgery Foundation clinical practice guideline[132] stress the need to identify children at risk for speech, language, and cognitive impairment early in the course of disease. The guidelines focus on children with sensory, physical, cognitive, or behavioral features that are likely to increase the risk of developmental difficulties (Box 29.1) and therefore warrant earlier hearing and language assessment and tympanostomy tube insertion. For otherwise healthy children, watchful waiting for up to 6 months with hearing evaluation at 3 months is suggested.

Box 29.1

Comorbid Conditions Associated With Increased Risk of Developmental Difficulties in Children With Otitis Media With Effusion

Permanent hearing loss independent of otitis media with effusion

Suspected or confirmed speech and language delay or disorder

Autism spectrum disorder and other pervasive developmental disorders

Syndromes (e.g., Down) or craniofacial disorders that include cognitive, speech, or language delays

Blindness or uncorrectable visual impairment

From Rosenfeld RM, Schwartz SR, Pynnonen MA, et al. Clinical practice guideline: tympanostomy tubes in children. Otolaryngol Head Neck Surg 2013;149:S1.

The primary intervention for OME is surgical. Antihistamines and decongestants are ineffective, and therapy with antibiotics or corticosteroids does not result in lasting benefit.[133–135]

Otitis Externa and Necrotizing Otitis Externa

Thomas G. Boyce, Karthik Balakrishnan

Otitis Externa

Epidemiology and Clinical Manifestations

Otitis externa is infection of the skin of the hairy and glabrous parts of the ear canal. Acute otitis externa (i.e., swimmer's ear) is usually unilateral and is often associated with head immersion in water. Any source of prolonged ear canal moisture can cause otitis externa, including hearing aid use and drainage from otitis media with a perforated tympanic membrane. Other predisposing factors include radiation exposure and immunocompromise.

In temperate climates, the disease peaks in the summer. When the skin of the ear canal is wet for prolonged periods, local defense mechanisms are impaired. Cerumen, which has antimicrobial properties,[1] is washed away; the thickness of the keratin layer is reduced; the pH of the canal increases; the skin may become macerated; and microscopic fissures develop. This can cause itching of the ear canal that may predispose to further trauma from cotton-tipped buds.[2] Gram-negative bacteria, most commonly *Pseudomonas* spp., flourish in the moist environment and invade superficial layers of skin.[3–5]

The ensuing inflammatory dermatitis progresses through three stages.[6,7] Each is associated with pain and tenderness exaggerated by movement of the tragus or pinna. In *mild otitis externa*, pain is ameliorated by simple analgesics. Skin of the hairy part of the ear canal is erythematous but not edematous.

In *moderate otitis externa*, there is increasing pain. The patient resists insertion of anything into the ear canal. The skin of the hairy part of the ear canal is intensely red under the macerated pieces of desquamated skin. Edema of the canal skin increases, and the canal lumen is narrowed to less than 50% of its normal diameter, obscuring the tympanic membrane.

Severe otitis externa is characterized by intense pain, often requiring narcotics; inflammatory edema, which narrows the external auditory meatus to barely admit a nasopharyngeal swab; and desquamated debris that precludes visualization of the tympanic membrane. Granulation tissue also may be seen in the ear canal. The patient may or may not have otorrhea, and the auricle can be swollen and painful.[7] In advanced cases, tender preauricular or postauricular lymphadenopathy, protrusion of the auricle, and contiguous cellulitis of the skin overlying the mastoid area can be seen. Unlike acute mastoiditis, the entire auricle not only protrudes but also is edematous, and the posterior auricular sulcus is preserved. Suctioning of the ear canal is difficult to perform without adequate analgesia.

Advanced cases of otitis externa are difficult to differentiate from necrotizing otitis externa, which is a perichondritis of the cartilaginous outer third of the ear canal.[8–10] It also can be difficult to distinguish from noninfectious disorders involving the ear canal, including malignancies (e.g., rhabdomyosarcoma), Langerhans cell histiocytosis, and Wegener granulomatosis.

Etiologic Agents

In healthy individuals, the ear canal microflora includes coagulase-negative staphylococci, corynebacteria, and micrococci. With prolonged exposure to water, gram-negative bacteria predominate.[3] *Pseudomonas aeruginosa* is responsible for most cases of otitis externa associated with swimming or due to persistent otorrhea from a patent tympanostomy tube. Other gram-negative bacteria occur less commonly. *Staphylococcus aureus* may be increasing in incidence.[11] *S. aureus* and *Streptococcus pyogenes* are the usual causes of acute otitis externa that occurs as an extension of a focal infection.[12]

Fungi are uncommon causes of otitis externa, in most series comprising less than 5% of cases.[13] However, in some studies, fungi constitute a higher proportion of isolates.[14] *Aspergillus* spp. account for about two thirds, and *Candida* spp. account for the remainder.[15] Prolonged use of topical antibacterials appears to be a risk factor for otomycosis.[15,16]

Viruses rarely cause otitis externa. Reactivation of latent varicella-zoster virus in the seventh cranial nerve results in herpes zoster oticus, which is characterized by unilateral otalgia, auricular vesicles, and hearing and vestibular symptoms. When these findings are associated with a peripheral facial paralysis, the complex is known as Ramsay Hunt syndrome.[17]

Key Points

Diagnosis and Management of Otitis Externa

Epidemiology and Clinical Manifestations

- Commonly associated with swimming
- Any source of prolonged ear canal moisture can lead to otitis externa.
- Manifests with pain on movement of the tragus or pinna

Etiologic Agents

- *Pseudomonas aeruginosa* is the most common cause.
- *Staphylococcus aureus* is also common.

Management

- Mild cases are treated with topical antibiotic drops (with or without glucocorticoids) and analgesics.
- Moderate or severe cases require aural lavage by an

otorhinolaryngologist.

Prevention

- Otitis externa after swimming can be prevented by thorough drying of the ear canal.
- Prompt treatment of acute otorrhea in patients with tympanostomy tubes with antibiotic-glucocorticoid drops can prevent secondary otitis externa.

Management

Mild cases of otitis externa can be treated with instillation of topical otic antibiotic drops. Culture of otorrhea is usually unnecessary. The patient can enter the swimming pool as long as prolonged submersion is avoided. Excess water should be drained from the ear canal and the ear canal dried thoroughly with a hair dryer.

In addition to adequate analgesia, moderate or severe otitis externa usually requires aural lavage of the ear canal to permit contact of the antibiotic drops with infected skin. This is best accomplished by referring the patient to an otorhinolaryngologist. Lavage may be performed daily in some cases, and close follow-up is essential. A wick sometimes is inserted into the canal to allow topical antibiotic drops to remain in contact with the wall, particularly if canal edema makes instillation of drops difficult. Individuals with moderate or severe otitis externa should avoid swimming and maintain dry ear precautions until inflammation subsides, although formal data on the effect of water precautions are lacking.

Available topical otic antibiotic drops include ofloxacin, ciprofloxacin with hydrocortisone or dexamethasone, and polymyxin B–neomycin–hydrocortisone. The use of corticosteroids is empiric. Topical steroid alone is inferior to antibiotic-steroid combinations.[18] A Cochrane database review found that the topical antibiotic preparations available were equally effective and that all were superior to placebo.[19] Systemic antibiotics are unnecessary for uncomplicated cases.[20]

Neomycin, Neosporin

Neomycin is an aminoglycoside and is ototoxic. It should not be administered unless the tympanic membrane is known to be intact. It may also cause a contact dermatitis in some patients. However, in a trial comparing ciprofloxacin-dexamethasone with polymyxin B–neomycin–hydrocortisone, adverse events were uncommon and were not different in the two groups.[21] Polymyxin B–neomycin–hydrocortisone is administered three to four times daily, ciprofloxacin-containing drops are administered twice daily, and ofloxacin drops can be administered once daily with equivalent cure rates.[22] Most patients can be treated with a 7-day course. Symptoms improve within 3 to 6 days of starting therapy. For patients who do not respond, physicians should consider the possibility of necrotizing otitis externa, particularly in immunocompromised hosts. Guidelines for the management of acute otitis externa have been published by the American Academy of Otolaryngology–Head and Neck Surgery Foundation.[23]

For the patient who fails to respond to empiric therapy, fungal infection should be considered. Otomicroscopic examination may reveal fungal elements, and a Gram stain of exudate may reveal the hyphae of *Aspergillus* spp. or the budding yeast of *Candida* spp. A 1% solution of clotrimazole is the most commonly used agent for otomycosis.[24] It has excellent activity against *Aspergillus* and *Candida*.[25] Nontuberculous mycobacteria may rarely be the cause of persistent tympanostomy tube otorrhea.[26] Furunculosis and local cellulitis respond best to the application of warm compresses and an orally administered antibiotic directed against *S. aureus.*

Prevention

After immersion, swimmers prone to recurrent otitis externa may benefit from thorough drying of the ear canals with a hair dryer. The prophylactic instillation of 2% acetic acid can be used to reduce *Pseudomonas* colonization.[27]

Prompt treatment of acute otorrhea in children with tympanic membrane perforation or tympanostomy tubes can prevent the development of secondary otitis externa. In a randomized trial, antibiotic-glucocorticoid drops were superior to oral amoxicillin-clavulanate or observation in resolving otorrhea.[28]

Necrotizing Otitis Externa

Epidemiology and Clinical Manifestations

Necrotizing (i.e., malignant) *otitis externa* results from invasive infection of the cartilage and bone of the external ear canal. A more accurate term is *skull base osteomyelitis due to otitis externa*.[29] Infection begins in the external auditory canal and spreads to the skull base through the fissures of Santorini, small perforations in the cartilaginous portion of the canal.[30] Infection then spreads along venous channels and fascial planes. The compact bone of the skull base becomes replaced with granulation tissue, causing bone destruction. Mastoid involvement is common.

Necrotizing otitis externa occurs most frequently in adults with diabetes mellitus. In a review of 46 adult cases, two thirds of patients were diabetic.[31] In contrast, a series of 14 pediatric cases reported only 21% with diabetes.[32] Other predisposing factors include immune deficiency, especially due to AIDS; chemotherapy-induced neutropenia; and functional neutrophil disorders.[33,34] It can be the presenting manifestation of malignancy.[35] Rarely, patients without risk factors are affected.[36]

The presenting symptoms are severe otalgia and otorrhea; both occur in more than 90% of patients.[31] About 25% of patients have facial nerve palsy at presentation, and children may be at higher risk for facial palsy.[30] This finding indicates further extension of the disease into the skull base, but its prognostic value is unclear.[37,38] Physical examination reveals purulent otorrhea with a swollen, tender external auditory canal. Granulation tissue or exposed bone is seen on the floor of the canal at the bone-cartilage junction.[30] Patients are often afebrile and have a normal leukocyte count, although the erythrocyte sedimentation rate is usually elevated. For children, the presentation is more acute, and they are more often febrile.

The initial manifestations of necrotizing otitis externa can mimic those of otitis externa, and clinicians must be aware of this possibility in the high-risk host. The diagnosis in a patient not known to have risk factors should prompt testing for diabetes and immune deficiency.

Imaging studies used include computed tomography (CT), magnetic resonance imaging (MRI), bone scans, and gallium scans. CT is sensitive in detecting bone erosion and decreased skull base density.[30] It is also sensitive in diagnosing abscess formation and involvement of the mastoid (Fig. 30.1). However, it is inadequate for demonstrating intracranial extension and marrow involvement. MRI is superior in showing soft tissue changes, dural enhancement, and involvement of the medullary bone spaces.[39] A technetium bone scan is highly sensitive, including early in the course of infection, but it is nonspecific and may remain positive for a prolonged period.[40] Gallium scans, which have similar sensitivity, are more useful for monitoring the response to therapy.[40]

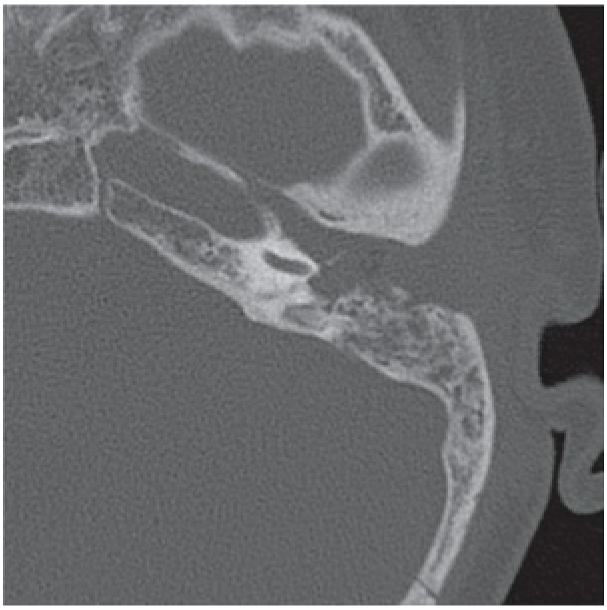

FIGURE 30.1 A 21-year-old man with medulloblastoma and chemotherapy-induced neutropenia had a 10-day history of severe left ear pain, otorrhea, and facial palsy. Axial, noncontrast computed tomography depicts soft tissue opacification of the left external auditory canal and opacification of the left middle ear and mastoid air cells. Irregularity and erosion of the posterior margin of the osseous left external auditory canal suggests osseous invasion and mastoid osteomyelitis consistent with necrotizing otitis externa. Intraoperative cultures of specimens obtained during debridement of the left mastoid grew *Pseudomonas aeruginosa*.

Complications result from contiguous spread to nearby structures. Spread to the stylomastoid foramen results in facial nerve palsy. Less commonly, involvement of the jugular foramen results in palsies of the glossopharyngeal, vagus, and accessory nerves. Septic thrombophlebitis of the internal jugular vein and of the sigmoid sinus may occur. Intracranial extension can result in meningitis, cerebral abscess, or dural sinus thrombosis, all of which portend a poor prognosis.[29]

Etiologic Agents

P. aeruginosa is by far the most common cause of necrotizing otitis externa, especially in patients with diabetes.[31] *S. aureus* is the second most common cause. *Aspergillus* spp., most commonly *A. fumigatis*, are sometimes isolated, particularly in patients with advanced AIDS.[31]

Key Points

Diagnosis and Management of Necrotizing Otitis Externa

Epidemiology and Clinical Manifestations

- Invasive infection of the cartilage and bone of the external ear canal
- Predisposing factors include diabetes mellitus, AIDS, neutropenia, other immune deficiency
- Manifested by severe otalgia and otorrhea; sometimes by facial palsy
- Usually diagnosed by computed tomography or magnetic resonance imaging

Etiologic Agents

- *Pseudomonas aeruginosa* is the most common cause.
- *Staphylococcus aureus* is also common.
- Occasionally, *Aspergillus* spp. are isolated.

Management

- Limited surgery to obtain cultures and to debride necrotic tissue
- Aggressive surgical resection is avoided.
- Empiric parenteral antibiotic therapy (e.g., cefepime, gentamicin) to cover *Pseudomonas*

Management

In the past, necrotizing otitis externa was managed surgically. Currently, most cases are effectively treated with prolonged courses of antibiotics. However, surgery still plays a critical role in two aspects: obtaining tissue samples for culture and histology and for local debridement of necrotic tissue. In contrast, more aggressive surgical resection may propagate infection.

Initial empiric therapy should be directed toward coverage of *P. aeruginosa* and *S. aureus*. Using two agents with antipseudomonal activity, such as cefepime and gentamicin, is prudent initially. Fluoroquinolones should be avoided if the patient recently received topical fluoroquinolone therapy because the incidence of resistance is high.[31,41] Vancomycin can be used for initial staphylococcal coverage. If patients fail to improve on initial therapy and adequate debridement has occurred, imaging to assess extension of infection should be considered. The possibility of infection by a filamentous fungus should be entertained and empiric antifungal therapy started with liposomal amphotericin or voriconazole. The duration of therapy usually is at least 6 weeks, although some patients are switched to oral therapy earlier.[30] Hyperbaric oxygen therapy has been proposed as an adjuvant to antimicrobial therapy, although high-quality data are lacking.[42]

Prognosis

Once a condition with a case-fatality rate of 50%,[43] necrotizing otitis externa is now cured in approximately 95% of patients.[31] Poor prognostic factors include intracranial extension, advanced underlying disease, and infection with *Aspergillus* spp.[29] In contrast to adults with necrotizing otitis externa, facial nerve paralysis in children is usually not reversible. Children are also more likely to experience permanent hearing loss from ossicular destruction.[10,32]

Mastoiditis

Ellen R. Wald, James H. Conway

Acute Mastoiditis

Acute mastoiditis is exclusively a complication of acute otitis media (AOM). Previously, only one third of cases occurred in the context of a first episode of otitis media[1]; more recently, acute mastoiditis has been the first evidence of otitis media in at least 50% of affected children.[2,3]

The incidence of mastoiditis declined remarkably after the introduction of antibiotics. Where antibiotic use for AOM has been systematically restricted, the incidence of acute mastoiditis may be higher, although it remains a relatively unusual occurrence.[4–6] In some settings such as Sweden, where antibiotic therapy for AOM in children younger than 2 years of age may be delayed under a watchful waiting approach with close supervision, no significant increase in acute mastoiditis has been reported.[7] However, when acute mastoiditis cases do occur, intracranial and extracranial complications frequently are observed.[3,8,9]

Pathogenesis

Mastoiditis is inflammation of the mastoid air cells in the temporal bone. Knowledge of the anatomy of the middle ear and mastoid is essential to understand the clinical manifestations of mastoiditis and its complications. Fig. 31.1 shows the relationships among the eustachian tube, middle ear, and mastoid. At birth, the mastoid consists of a single air cell, the antrum, which is connected to the middle ear by a narrow channel, the aditus ad antrum.[10] As the child grows, the mastoid bone becomes pneumatized, resulting in a series of interconnected air cells that are lined by modified respiratory epithelium.

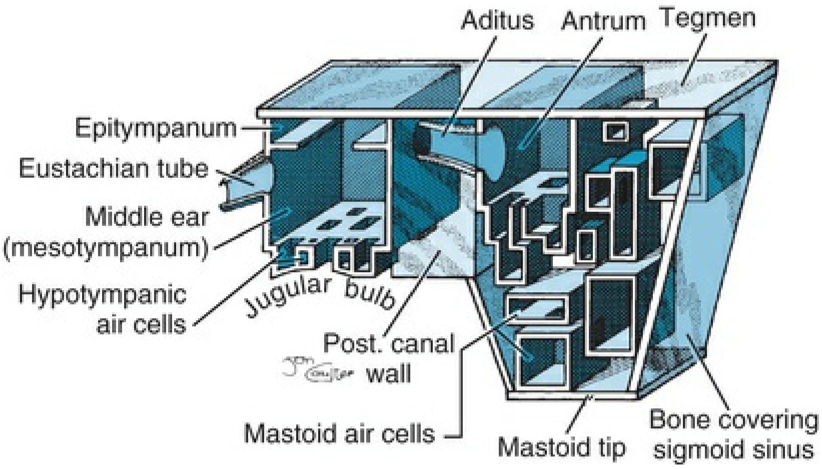

FIGURE 31.1 Schematic representation of the anatomy of the middle ear and mastoid air cell system. The aditus ad antrum is the narrow connection between the two; it may be a site of obstruction inhibiting drainage into the middle ear. (From Bluestone CD, Klein JO. Intratemporal complications and sequelae of otitis media. In: Bluestone CD, Simons JP, Healy GB (eds). Pediatric Otolaryngology, 5th ed. Shelton CT, People's Medical Publishing House-USA, 2014. pp. 781–847.)

When AOM develops as a result of eustachian tube dysfunction, there is an acute inflammatory response of the mucosa lining the middle ear and, in many cases, the mastoid.[11] Most episodes of AOM respond to antibiotic therapy. Eustachian tube dysfunction resolves, and the mucosa of the middle ear and mastoid recovers. In rare cases of newly diagnosed AOM or in cases of inadequate or inappropriate treatment, inflammation of the middle ear and mastoid persists. Histopathologic specimens from children who undergo mastoidectomy for acute or chronic mastoiditis demonstrate similar subacute or chronic infectious changes.[12] Serous and then purulent material accumulates within the mastoid cavities. As the pressure increases, the thin bony septa between air cells may be destroyed (i.e., acute coalescent mastoiditis).[10] This may be followed by formation of abscess cavities and ultimately by the dissection of pus into adjacent areas.

The direction in which purulent material dissects determines the clinical presentation and complications associated with acute mastoiditis (Box 31.1). Pus traversing the aditus ad antrum reaches to the middle ear and empties through the eustachian tube (with resolution of the process) or a perforation of the tympanic membrane. If the pus erodes the lateral cortex of the mastoid, a subperiosteal abscess is produced. The abscess results in swelling or fluctuation above the auricle in infants (when erosion comes from the zygomatic mast cells) or behind the lower earlobe over the mastoid process in older children.[8] Rarely, erosion occurs through the medial aspect of the mastoid tip, resulting in a neck abscess beneath the attachment of the sternocleidomastoid and digastric muscles (i.e., Bezold abscess).[13]

Box 31.1

Deafness

Labyrinthitis

Intracranial

Meningitis

Temporal lobe or cerebellar abscess

Epidural empyema

Subdural empyema

Venous sinus thrombosis

Pus can dissect medially to the petrous air cells (in the 20% of the population in which there is pneumatization), resulting in petrositis, or posteriorly to the occipital bone, resulting in osteomyelitis of the calvarium (i.e., Citelli abscess).[10] Purulent material can spread to the labyrinth and facial nerve. Pus within the mastoid can dissect toward the inner cortical bone, causing suppurative complications in the central nervous system, such as meningitis; epidural, subdural, temporal lobe, or cerebellar abscesses; and venous sinus thrombosis.

Clinical Presentation

The clinical presentation of the patient with mastoiditis depends on the patient's age and the stage of the osteitis (i.e., uncomplicated or already evolved to a subperiosteal abscess). Uncomplicated infection in a child younger than 2 years manifests as fever, otalgia or irritability, retroauricular pain, swelling, erythema, and a downward and outward deviation of the auricle (Fig. 31.2).[8] In most cases, otorrhea or a bulging, immobile, opaque tympanic membrane is observed. There may be sagging of the posterosuperior wall of the external auditory canal. In rare instances with obstruction at the aditus ad antrum, middle ear infection clears through the eustachian tube, but the mastoid, unable to drain, continues to suppurate.

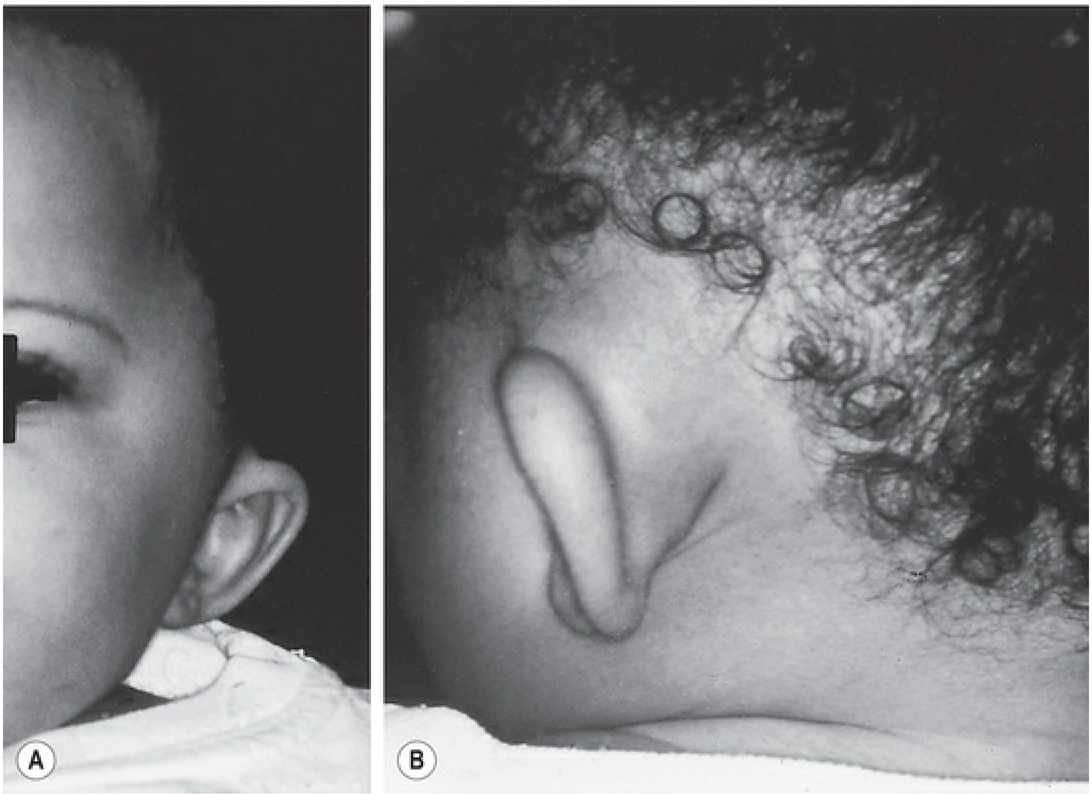

FIGURE 31.2 A 13-month-old toddler with a 10-day history of acute otitis media unresponsive to amoxicillin therapy. (A and B) There is erythema and edema above the left ear with downward, outward, and anterior displacement of the pinna.

In children older than 2 years, the pinna usually is deviated upward and outward because the inflammatory process frequently concentrates over the mastoid process. When subperiosteal pus has accumulated, a fluctuant, erythematous, and tender mass can be found overlying the mastoid bone in all age groups.

Considerable attention has been given in the past 2 decades to the entity called *masked mastoiditis* or *subacute mastoiditis*.[14] The patient typically has had persistent middle ear effusion or recurrent episodes of acute otitis media without sufficient antimicrobial therapy. In either case, there is a low-grade but persistent infection in the middle ear and mastoid with osteitis. Masked mastoiditis can manifest as fever, otalgia, and an abnormal tympanic membrane or occasionally manifest with an extracranial or intracranial complication.

Microbiology

The most recent prospective study of the microbiology of acute mastoiditis in children was published in 1987.[15] Precise delineation of the microbiology has been hampered by routine antibiotic therapy before clinical presentation. Most existing series published in the antibiotic era are retrospective reviews.[1–3,8,14,16–25]

Clinical specimens should be obtained from the middle ear by tympanocentesis or by aspiration through a tympanostomy tube or perforation after careful sterilization of the surrounding structures. Cultures obtained from the external canal without careful sterilization can be contaminated with *Pseudomonas aeruginosa, Staphylococcus aureus,* and other colonizing organisms. Culture of the cerebrospinal fluid is valuable in cases of bacterial meningitis. Blood cultures rarely are positive. Percutaneous aspiration of a subperiosteal abscess should be undertaken, particularly if definitive surgery will be delayed. Materials from abscesses (i.e., brain, epidural, or subdural) that are drained or aspirated should be submitted for Gram stain and aerobic and anaerobic cultures.

In contrast to the usual pathogens that cause AOM (i.e., *Streptococcus pneumoniae, Haemophilus influenzae,* and *Moraxella catarrhalis*),[26] the bacterial species most often implicated in acute mastoiditis are *S. pneumoniae, S. pyogenes, P. aeruginosa,* and *S. aureus* (Table 31.1). *P. aeruginosa* rarely is a true pathogen in acute mastoiditis. Exaggerated rates of recovery may reflect the sampling method for culture from the external canal.[22] Except for a single prospective study in which anaerobic bacteria predominated,[15] *H. influenzae,* Enterobacteriaceae bacteria, mycobacteria, and anaerobic organisms are recovered only occasionally.

TABLE 31.1

Bacteriology of Cases of Acute Mastoiditis in Children (1955–2009)[a]

Bacterial Species	Number	Percentage
Streptococcus pneumoniae	230	32
Streptococcus pyogenes	121	17
Staphylococcus aureus	62	9
Other gram-positive cocci[b]	26	4
Haemophilus influenzae	34	5
Pseudomonas aeruginosa	119	16
Other gram-negative bacilli[c]	29	4
Anaerobic bacteria[d]	72	10
Mycobacterium tuberculosis	31	4
Total isolates	724	100

[a] Many patients received antimicrobial therapy before specimens were obtained for culture. Isolates were obtained from blood, myringotomy aspirate, external auricular drainage, subperiosteal aspirate, cerebrospinal fluid, or surgical specimens.

[b] Viridans streptococci, enterococci, and coagulase-negative staphylococci.

[c] *Citrobacter freundii*, *Escherichia coli*, *Enterobacter* spp., *Acinetobacter* spp., *Klebsiella* spp.

[d] *Bacteroides* spp., *Fusobacterium nucleatum*, and microaerophilic streptococci.

Data from references 1–3, 8, 12, and 16–25.

The introduction of heptavalent pneumococcal conjugate vaccine (PCV7) has not affected the proportion of acute mastoiditis cases caused by *S. pneumoniae*[24] typically related to an increase in serotype 19A as the predominant serotype isolated from mastoid cultures.[27] Although there appeared to be an initial decline in the incidence of acute mastoiditis after the introduction of PCV7 in Australia, Israel, and some areas of the United States, it did not persist, and recent reports suggest that the incidence rates have returned to prevaccination rates.[28–30] The effect of PCV10 and PCV13 on the incidence and microbiology of mastoiditis requires ongoing study.

Diagnosis

The diagnosis of mastoiditis usually is made clinically, without need for imaging studies (Box 31.2). Some studies have shown that outcomes are similar for patients with acute mastoiditis regardless of whether computed tomography (CT) scans are performed.[31] A systematic review of more than 1000 articles identified the clinical signs most frequently used to diagnose acute mastoiditis as postauricular swelling, erythema, tenderness, and protrusion of the auricle.[32] High-grade fevers and elevated inflammatory markers such as absolute neutrophil counts and C-reactive protein levels can suggest more complicated infections.[25]

Box 31.2

Diagnosis of Acute Mastoiditis

Fever, otalgia, postauricular swelling plus redness

- Older child: ear up and out
- Infant: ear down and out

Tympanic membrane: acute otitis media

Radiograph: mastoid air cells coalescent or clouded

Computed tomography, magnetic resonance imaging, or bone scan as needed

If plain radiographs are obtained, they often show clouding of the mastoid or coalescence of air cells (i.e., dissolution of thin bony septa from increased pressure and ischemia). Clouding of the mastoid is not diagnostic of acute mastoiditis and is observed in at least 50% of patients with uncomplicated AOM. Coalescent mastoiditis is a diagnostic radiographic finding, but it is seen in few patients. Plain radiographs in cases of acute and even complicated mastoiditis have been normal.[1,33]

CT imaging usually is more helpful when there are intracranial complications or for patients suspected of having masked mastoiditis.[13,22] CT evidence of mastoiditis consists of haziness or destruction of the mastoid outline and loss of or decrease in sharpness of the bony septa that define the mastoid air cells (Fig. 31.3).[10] Cloudiness in areas normally pneumatized, which can be seen in uncomplicated AOM, is not diagnostic of mastoiditis (Fig. 31.4).

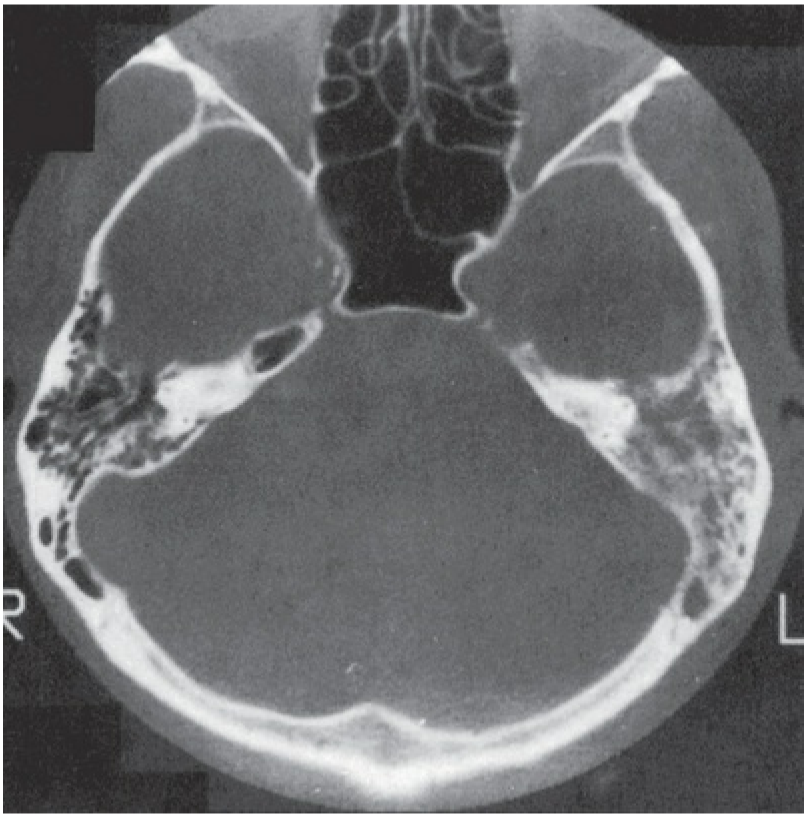

FIGURE 31.3 Computed tomography of a child with acute mastoiditis shows coalescence and destruction of septa between the mastoid air cells.

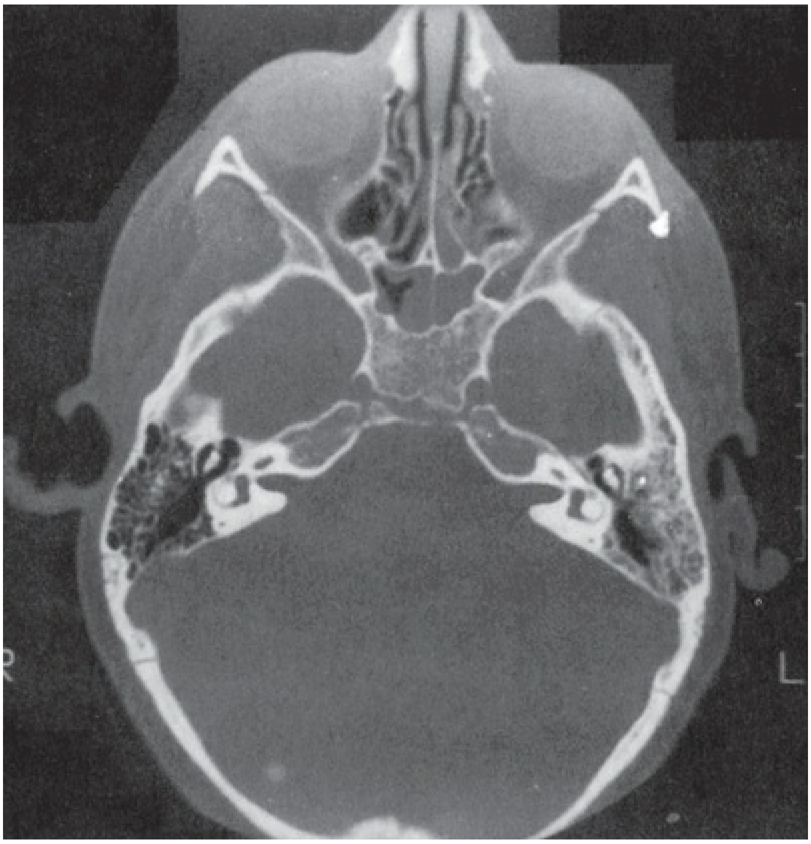

FIGURE 31.4 Computed tomography of a child with acute otitis media shows clouding of the mastoid without bony destruction.

Lytic lesions of the temporal bone and soft tissue abscess sometimes can be seen (Fig. 31.5). For bony destruction to be appreciated, 30% to 50% of bone must be demineralized. When CT shows cloudiness, a technetium-99 bone scan, which is more sensitive to osteolytic changes, may be useful.[34]

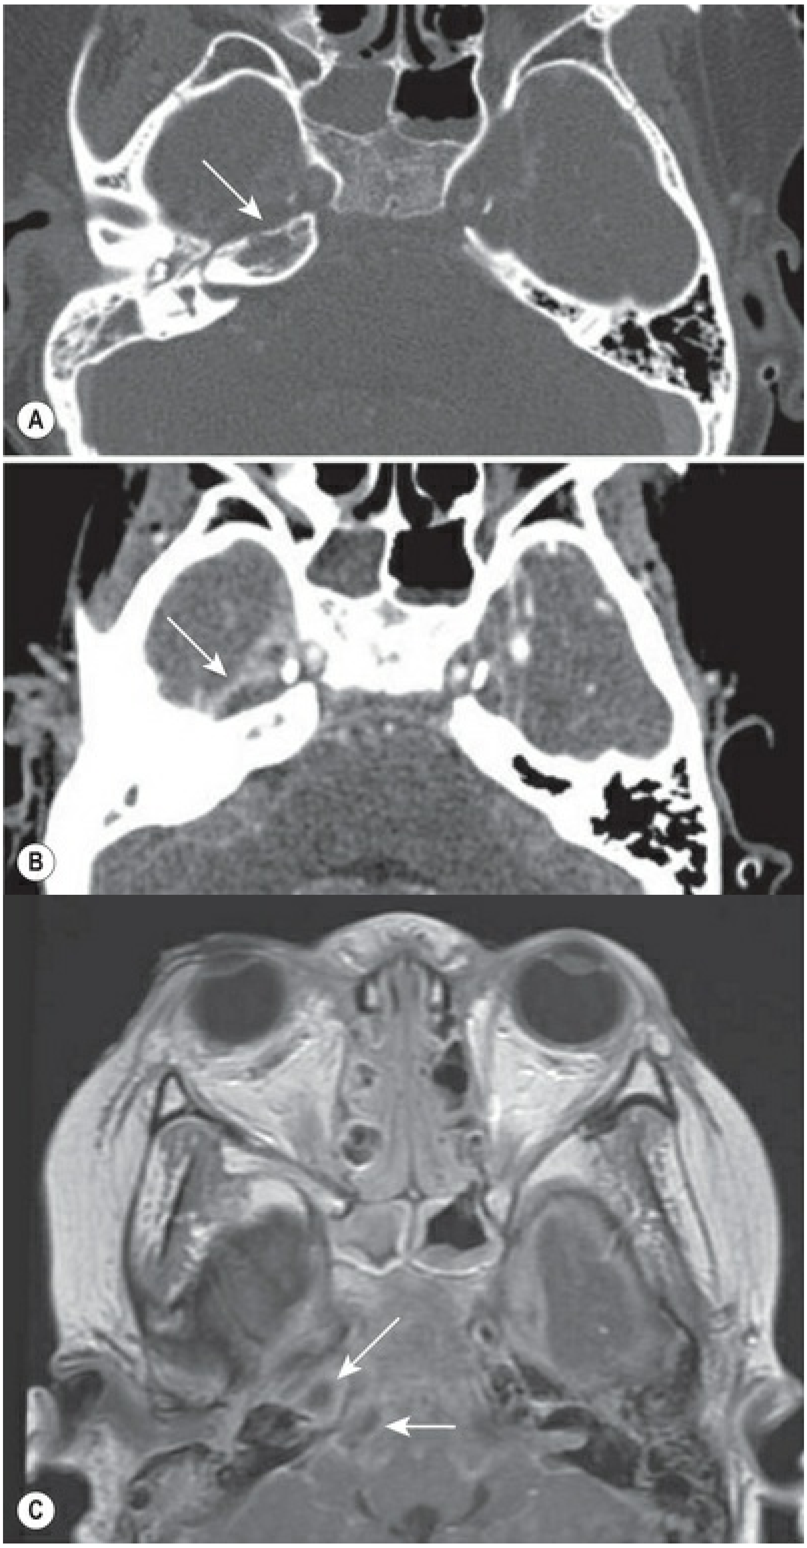

FIGURE 31.5 Case of a 6-year-old boy with Gradenigo syndrome. (A) Noncontrast computed tomography (CT) shows expansion and erosion of the apex of the petrous portion of the right temporal bone *(arrow)* and mastoid coalescence. (B) Contrast-enhanced CT shows an abscess with rim enhancement along the superior border of the petrous apex with an anterior extension *(arrow).* (C) Contrast-enhanced, T1-

weighted, axial magnetic resonance imaging shows hypointense abscesses with rim enhancement around the petrous bone *(long arrow)* and in the right anterior pons *(short arrow)*. (Courtesy of E.N. Faerber, St. Christopher's Hospital for Children, Philadelphia, PA.)

CT with enhancement or magnetic resonance imaging (MRI) is recommended for patients with suspected vascular thrombosis as a complication of mastoiditis. MRI with gadolinium enhancement confirms the diagnosis and delineates the extent of suspected disease[35] because of its higher sensitivity for detection of extra-axial fluid collections and associated vascular complications.[36]

Complications

Complications of mastoiditis are related to the spread of infection or inflammation from the middle ear or mastoid to contiguous structures and occur in 7% to 16% of cases.[18,22] Suppurative labyrinthitis (resulting in deafness), Bezold abscess, and cranial osteomyelitis are infectious complications. Facial paralysis can result from infection or inflammation of the facial nerve as it traverses the petrous bone. If infection spreads to the petrous bone, Gradenigo syndrome can follow, characterized by cranial nerve VI palsy, pain in the distribution of the trigeminal nerve (i.e. eye pain), and otorrhea. Intracranial complications include epidural or subdural empyema, cerebellar or temporal lobe abscess, meningitis, and venous thrombosis.

Management

Treatment of uncomplicated mastoiditis includes intravenous antimicrobial therapy and usually myringotomy, with or without placement of a tympanostomy tube. When possible, tympanocentesis should be performed if there is an intact tympanic membrane to ascertain the microbiologic profile and antimicrobial susceptibility.[10] The same treatment is appropriate when facial paralysis occurs as an isolated complication.[10]

If the child does not improve in 48 hours (i.e., evidenced by diminution of systemic and local findings), a simple mastoidectomy may be required. Simple mastoidectomy in combination with antimicrobial therapy and tympanostomy tube placement usually is indicated as initial management when a subperiosteal abscess exists. Radical mastoidectomy only is performed when there is no response to simple mastoidectomy, as evidenced by continued otorrhea.[10]

This stepwise approach continues to prove effective, and publications support a conservative approach that reserves more invasive surgical procedures for selected patients who are failing to improve. Groups from France, Israel, and Sweden have performed retrospective reviews that endorse a standardized approach to assessment and reserve mastoidectomy for patients who fail to improve or have significant abscesses.[37–39]

Several agents are appropriate for the intravenous treatment of acute mastoiditis. Empiric antibiotic therapy should provide coverage for common bacterial pathogens (see Table 31.1). Cefepime (100–150 mg/kg/day in doses divided every 8–12 hours), ceftazidime (150 mg/kg/day in divided doses every 8 hours), or piperacillin-tazobactam (240 to 300 mg/kg/day [piperacillin component] in divided doses every 6 to 8 hours [not approved for use in patients younger than 12 years]) is suitable. In a penicillin-allergic patient, clindamycin (40 mg/kg/day in divided doses every 6 hours) plus aztreonam (120 mg/kg/day in divided doses every 8 hours) can provide coverage for gram-positive and gram-negative pathogens. The addition of vancomycin (60 mg/kg/day in divided doses every 6 hours) should be considered for children who are severely ill with concerns about secondary bacterial meningitis and for those at high risk for resistant pneumococcal infection caused by penicillin-resistant pneumococci or methicillin-resistant *S. aureus*. Immunization history and consideration of local resistance data are important in determining optimal antibiotic choices.

If the Gram stain of aspirated material demonstrates an unexpected finding, additional antimicrobial agents are considered (e.g., for brain abscess). When results of culture and susceptibility tests are available, therapy is adjusted. Intravenous treatment should be maintained for at least 7 to 10 days. If the clinical response to treatment has been satisfactory, oral antimicrobial therapy can be substituted to complete a 4-week course. Prolonged courses of intravenous therapy usually are unnecessary in the absence of central nervous system extension of infection. Placement and maintenance of indwelling vascular catheters increase the cost of therapy significantly and come with associated risks.[40]

Chronic Mastoiditis

Pathogenesis

Chronic mastoiditis usually is the result of chronic suppurative otitis media (CSOM)[10] and is less frequently the result of inadequate management of acute mastoiditis. CSOM is characterized by long-standing (>3 weeks), painless otorrhea through a nonintact tympanic membrane (i.e., spontaneous perforation or patent tympanostomy tube) that is not responsive to the antibiotics customarily prescribed for patients with AOM (Box 31.3).[10,41] (See Chapter 30).

Box 31.3

Diagnosis of Chronic Mastoiditis

Otorrhea ≥3 wk

Nonintact tympanic membrane (perforation or patent tympanostomy tube)

Nonresponsive to usual antibiotics

Etiology

- Pseudomonads
- Staphylococci
- Other gram-negative bacilli

Complications

- Cholesteatoma
- Progressive mastoiditis

- Deafness (eighth nerve or ossicular)

A nonintact tympanic membrane is essential for pathogenesis, providing microbial species that colonize the external auditory canal access to the middle ear and ultimately the mastoid. These organisms cause a low-grade, persistent inflammatory response that is typically unaltered by conventional therapeutic agents for AOM. Although the inflammatory process is painless and patients rarely are febrile, CSOM can lead to chronic osteitis of the mastoid and complications such as hearing loss, cholesteatoma, facial nerve paralysis, meningitis, and brain abscess.

The microbiology of CSOM and chronic mastoiditis was documented during the 1980s–1990s (Table 31.2).[10,42–46] *P. aeruginosa* is the most common, followed by gram-negative enteric bacilli and *S. aureus. P. aeruginosa* and *S. aureus* occur together frequently.[10,42,47] With the exception of a single study, anaerobic flora are isolated only occasionally.[48] Rarely, *S. pneumoniae* or *H. influenzae* is causative.

TABLE 31.2

Bacteriology of Chronic Suppurative Otitis Media in 200 Children (1983–1992)

Bacterial Species	Number	Percentage
Pseudomonas spp.	176	58
Pseudomonas aeruginosa	171	
Other species	5	
Enteric gram-negative rods	50	16
Escherichia coli	8	
Enterobacter spp.	9	
Proteus spp.	17	
Others	16	
Staphylococcus spp.	41	13
Staphylococcus aureus	38	
Staphylococcus epidermidis	3	
Streptococcus pneumoniae	10	3
Haemophilus influenzae	10	3
Others	19	6

Data from references 42–46.

Mycobacterium tuberculosis was a common cause of mastoiditis in the early 1900s, manifesting as a chronically draining ear. This organism now is recovered very infrequently from patients with long-standing otorrhea.[49] Nontuberculous mycobacteria and *M. bovis* can produce an identical clinical syndrome. Most nontuberculous mycobacterial infections are thought to occur through the introduction of organisms through perforated tympanic membranes, emphasizing the need for good hygiene after tympanostomy tube placement.[50] *M. bovis,* which is not easily distinguished from *M. tuberculosis,* should be considered in patients who consume unpasteurized dairy products.[51]

Diagnosis

The diagnosis of CSOM usually is based on the typical clinical presentation of painless otorrhea unresponsive to conventional antibiotic therapy. The patient with CSOM is readily distinguished from the patient with a spontaneous perforation due to AOM, in whom systemic and local symptoms are prominent, and the response to antimicrobial management is brisk. The CSOM patient also must be differentiated from the child with otorrhea due to otitis externa in whom pressure on or movement of the tragus causes discomfort and the tympanic membrane is normal.

An otomicroscopic examination of the tympanic membrane should be undertaken by the otolaryngologist in the initial evaluation of chronic otorrhea.[47] This procedure, which may require general anesthesia, provides an opportunity to detect a cholesteatoma, retraction pocket, granulation tissue, polyp, or foreign body. A specimen should be obtained from the middle ear cavity without contamination from the external auditory canal and sent for Gram and acid-fast stains and culture for aerobic, anaerobic, and mycobacterial pathogens. A biopsy should be performed of any suspicious tissue protruding through the perforation or tympanostomy tube because rhabdomyosarcoma and neuroblastoma can manifest as CSOM or chronic mastoiditis, usually with associated cranial nerve palsies.[52] The tuberculin skin test (TST) should be performed when CSOM does not respond to standard antimicrobial therapy.

Management

Failure to respond to oral antibiotics is important in defining CSOM and suggests *P. aeruginosa* as the probable cause. Treatment of patients with CSOM often is initiated with topical antimicrobial agents and vigorous aural toilet, which consists of daily suctioning of the external auditory canal to permit delivery of topical therapy. When otorrhea is copious, ototopical therapy cannot be effective unless the external canal is cleared. Topical therapy is chosen because the bacteria isolated from patients with CSOM often are resistant to commonly prescribed oral antibiotics.

Ofloxacin otic solution (0.3%), a topical fluoroquinolone approved for use in children in 1999, has excellent activity against virtually all microbial species likely to be found in patients with CSOM.[41,53] It has shown no ototoxic effects when administered to adults or children.[54] A Cochrane database of systematic reviews performed to assess the effect of topical antibiotics without corticosteroids for patients with chronically draining ears and underlying eardrum perforations found topical quinolones significantly better for CSOM than antiseptics and no drug. Studies were inconclusive regarding differences between quinolone and nonquinolone antibiotics.[55] The aural discharge frequently clears within several days to 1 week after appropriate topical therapy is started.

If the CSOM does not respond to topical therapy, a course of intravenous antimicrobial therapy is appropriate. Comparison of regimens for the treatment of CSOM is confounded by differences in patient selection, causative agents, use of topical agents in conjunction with systemic therapy, frequency of aural toilet, and use of prophylactic antibiotics after completion of initial therapy. An appropriate choice for intravenous therapy is an antipseudomonal penicillin (e.g., piperacillin-tazobactam at 240 to 300 mg/kg/day in divided doses every 6 hours [not approved for use in children younger than 12 years]) or a third- or fourth-generation cephalosporin with antipseudomonal activity, such as ceftazidime (150 mg/kg/day in divided doses every 8 hours) or cefepime (100–150 mg/kg/day in doses divided every 8–12 hours).[41] Daily aural toilet is instituted for debridement and to assess cessation of drainage. Intravenous therapy should be continued at least 1 week after drainage has ceased because the middle ear mucosa is still likely to be inflamed and immediate relapse is possible.[56,57] If otorrhea persists despite parenteral therapy or recurs shortly after the cessation of intravenous therapy, a simple tympanomastoidectomy is required.

Several investigators have reported effectively treating CSOM in children with intravenous or intramuscular antibiotics (e.g., ceftazidime) on an outpatient basis, with daily return to the otolaryngologist for aural toilet.[46] Unfortunately, CSOM remains a neglected and difficult disease. There are few new data on prevention or treatment.[58]

Sinusitis

Ellen R. Wald, Gregory P. DeMuri

Upper respiratory tract infections (URIs) are the most common medical condition evaluated by primary practitioners who care for children. An estimated 5% to 10% of URIs in early childhood are complicated by acute bacterial sinusitis (ABS).[1] Children average 6 to 8 colds per year, and sinusitis is a common problem in clinical practice.

Pathogenesis

The respiratory mucosa that lines the nose is continuous with the mucosa that lines the paranasal sinuses. Secretions produced within the sinus cavities are delivered through the sinus ostia to the nose by normal mucociliary function. The maxillary, anterior ethmoid, and frontal sinuses drain to the middle meatus. The sphenoid and posterior ethmoid sinuses drain to the superior meatus.

Three key elements important to the normal physiology of the paranasal sinuses are patency of the ostia, function of the ciliary apparatus, and integral to the latter, quality of the secretions.[2] Retention of secretions in the paranasal sinuses usually results from one or more of the following conditions: obstruction of the ostia, reduction in the number of or impairment in the function of the cilia, and overproduction of or change in the viscosity of secretions.

Most cases of ABS are thought to be bacterial complications of viral URIs. The viral infection affects the mucosa of the nose, causing rhinitis, and often affects the mucosa of the sinuses. In most instances, the inflammatory response subsides spontaneously. In some cases, however, mucositis results in obstruction of the sinus ostia, impairment of the mucociliary apparatus, and alteration in the volume and quality of secretions.

The narrow caliber of the individual ostia that drain the maxillary and ethmoid sinuses sets the stage for obstruction to occur easily and often during the course of a viral URI. When obstruction occurs, there is a transient increase in intrasinus pressure. This is followed quickly by the development of negative pressure within the sinus cavities as the oxygen component of the intrasinus air is rapidly absorbed by the metabolically active mucosa. When the pressure in the sinuses is negative relative to normal atmospheric pressure in the nose, conditions favor aspiration of mucus heavily laden with bacteria from the nose or nasopharynx into the presumably sterile paranasal sinuses. Under ordinary circumstances, the contaminating bacteria would be swept out again by normal ciliary function. However, when ciliary function is impaired and sinus ostia are obstructed, bacteria multiply to high density and initiate an intense inflammatory response. Sneezing, sniffling, and nose blowing also alter intrasinus pressure and facilitate bacterial contamination of the paranasal sinuses. Intranasal pressures are extremely high during nose blowing, and nasal fluid can enter the maxillary sinus at that time.[3]

The factors predisposing to ostial obstruction can be divided into those that cause mucosal swelling due to systemic illness or local insults and those due to mechanical obstruction (Table 32.1). Although many conditions can lead to ostial closure, viral URI and allergic inflammation are by far the most common and most important.

TABLE 32.1

Factors Predisposing to Sinus Ostial Obstruction

Mucosal Swelling	Mechanical Obstruction
Systemic disorders	Choanal atresia
• Viral upper respiratory tract infection	Deviated septum
• Allergic inflammation	Nasal polyps
• Cystic fibrosis	Foreign body
Immune disorders	Tumor
• Ciliary dyskinesia	Ethmoid bulla
• Local insult	

• Facial trauma	
• Swimming, diving	
• Drug-induced rhinitis	
• Gastroesophageal reflux	

Clinical Manifestations

Viral Upper Respiratory Tract Infections

The course of most uncomplicated viral URIs is 5 to 10 days[4] (Fig. 32.1). Although the patient may not be free of symptoms on the 10th day, respiratory symptoms have peaked in severity on days 3 to 6 and begun to improve. Most patients with uncomplicated viral URIs do not have fever. However, if fever is present, it tends to occur early in the illness, often in concert with other constitutional symptoms such as headache and myalgia. Typically, fever and constitutional symptoms disappear in the first 24 to 48 hours, and respiratory symptoms become more prominent.

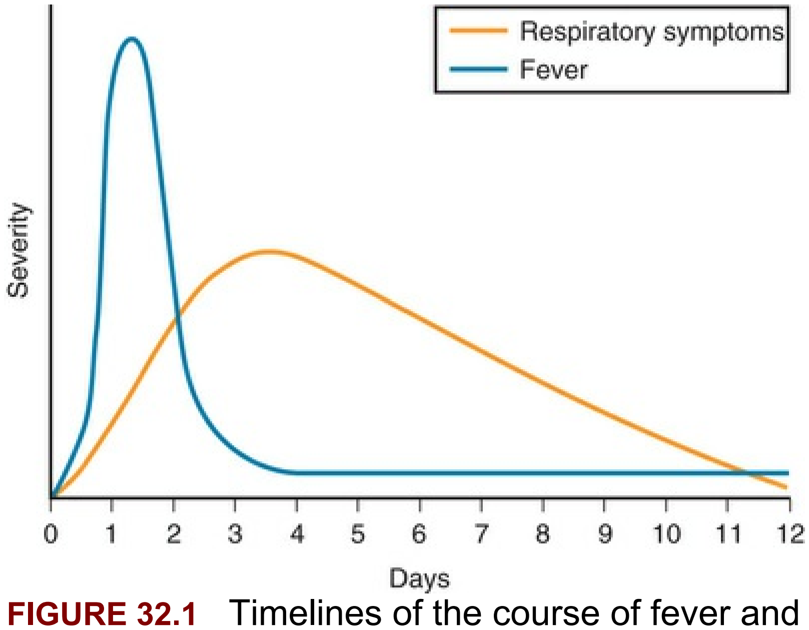

FIGURE 32.1 Timelines of the course of fever and respiratory tract symptoms in uncomplicated viral upper respiratory tract illness.

Viral URIs usually are characterized by nasal symptoms (i.e., discharge and congestion or obstruction) or cough, or both. Patients also may complain of a scratchy throat. The nasal discharge usually begins as clear and watery. Often, the quality of nasal discharge changes during the course of the illness. Typically, the nasal discharge becomes thicker and more mucoid and can become purulent (i.e., thick, colored, and opaque) for several days. The situation then reverses, with the purulent discharge becoming mucoid and then clear again or drying. The transition from clear to purulent to clear again occurs in uncomplicated viral URIs without the intervention of antimicrobial therapy.

Clinical Presentations of Acute Bacterial Sinusitis

Three clinical presentations of ABS can be described (Box 32.1).[5] The most common is onset with persistent symptoms.[6,7] Cardinal features are nasal symptoms (i.e., anterior or posterior nasal discharge, nasal obstruction, or congestion) or cough, or both, for more than 10 but fewer than 30 days and that do not improve. The latter qualifier is extremely important. Some individuals with uncomplicated viral URIs still have residual respiratory symptoms at the 10-day mark. To be considered a sign of ABS, these respiratory symptoms must persist without improvement.

Box 32.1

Clinical Manifestations of Acute Sinusitis

Persistent Symptoms

Nasal discharge and/or cough for >10 days and not improving

Severe Symptoms

High fever (≥39°C) and purulent nasal discharge together for >3 days

Worsening Symptoms

Resolving upper respiratory symptoms

Worsening on day 6 or 7 with new or recurrent fever or exacerbation of nasal symptoms and/or cough

The nasal discharge in patients with persistent symptoms can be of any quality (i.e., thick or thin, serous, mucoid, or purulent), and the cough, which may be wet or dry, must occur during the daytime, although it is often described as worse at night. Malodorous breath often is reported by parents of preschool children. Complaints of facial pain and headache are rare, although painless morning swelling of the eyelids occurs occasionally. The child may not appear very ill, and if fever occurs, it is usually low grade. Persistence rather than severity of symptoms brings the child to attention. Strict observance of this presentation results in a diagnosis of acute sinusitis for 6% to 7% of children with upper respiratory tract symptoms who are evaluated by primary care providers.[8,9]

The second presentation is characterized as onset with severe symptoms. Severity is described as a combination of high fever (≥38.5°C) and purulent nasal discharge occurring for at least 3 to 4 consecutive days.[7] Two features help distinguish this presentation from an uncomplicated viral URI. In ABS, the fever is higher and lasts longer, and the nasal discharge is purulent from the beginning of the illness.

The third presentation of ABS is worsening symptoms or a biphasic illness (i.e., *double sickening* in the Scandinavian literature).[7,10] Illness begins similar to an uncomplicated viral URI from which the patient seems to be recovering. On the 6th or 7th day of illness, the patient becomes substantially worse. The worsening symptoms can manifest as an increase in respiratory symptoms (i.e., exacerbation of nasal discharge or nasal congestion or daytime cough) or the new onset or recurrence of fever.

Patients with subacute or chronic sinusitis have a history of protracted (i.e., >30 days and not improving) respiratory symptoms. Nasal congestion (i.e., obstruction) and cough (i.e., day and night) are most common. Sore throat is a frequent complaint resulting from mouth breathing due to nasal obstruction. Nasal discharge of any quality and headache are less common, and fever is rare.

On physical examination, the patient with ABS can have mucopurulent discharge in the nose or posterior pharynx. The nasal mucosa usually is erythematous but can occasionally be pale and boggy; the throat can show moderate injection. Examination of the tympanic membranes can show evidence of acute otitis media or otitis media with effusion, which occurs more often in chronic than acute sinusitis. The cervical lymph nodes usually are not enlarged significantly or tender. Occasionally, there is tenderness with palpation or percussion over the paranasal sinuses or appreciable periorbital edema with soft, nontender swelling of the upper and lower eyelid and discoloration of the overlying skin. Facial tenderness, however, is not a sensitive or specific sign of sinusitis. Malodorous breath in the absence of pharyngitis, poor dental hygiene, or a nasal foreign body can suggest bacterial sinusitis. None of these characteristics, however, differentiates rhinitis from sinusitis.

Diagnostic Methods

Imaging

In cases of uncomplicated sinusitis, no confirmatory imaging is recommended.[7] Many studies have documented that when images of any kind (i.e., plain radiograph, computed tomography [CT], or magnetic resonance imaging [MRI]) are obtained in children or adults with uncomplicated viral URIs, most exhibit the same findings that in the past were associated with acute sinusitis (i.e., diffuse opacification, mucosal swelling, or an air-fluid level).[11–15] This is attributable to the continuity of the respiratory mucosa of the upper respiratory tract, which often is diffusely inflamed during a viral URI.

Although normal images can exclude sinusitis in patients with respiratory symptoms, abnormal images cannot confirm a diagnosis and are not indicated for uncomplicated infections. In contrast, when patients have complications of acute sinusitis (e.g., subperiosteal abscess, intracranial disease) or have protracted or nonresponsive symptoms, imaging (usually CT and occasionally MRI) is extremely helpful in clarifying the precise diagnosis and informing the necessity for surgical interventions.[7]

Sinus Aspiration

Although rarely done, maxillary sinus aspiration can be performed safely by a skilled otolaryngologist in the ambulatory setting using a transnasal approach (Fig. 32.2). Sedation or general anesthesia may be required for adequate immobilization of the young child. Current indications for maxillary sinus aspiration are a lack of response of sinusitis to multiple courses of antibiotics, severe facial pain, orbital or intracranial complications, and evaluation of an immunocompromised host.

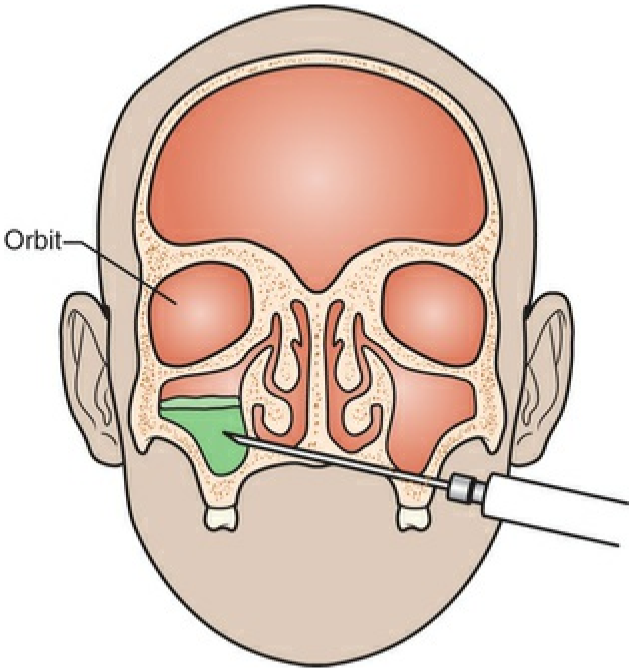

FIGURE 32.2 Coronal section of the nose and paranasal sinuses demonstrates how a maxillary sinus aspiration is performed. After sterilization of the mucosa beneath the inferior turbinate, a trocar is passed across the lateral nasal wall into the maxillary sinus.

There must be careful decontamination and anesthesia of the area beneath the inferior turbinate through which the trocar is passed. Material aspirated from the maxillary sinus should be sent for Gram stain and quantitative aerobic and anaerobic cultures. The recovery of bacteria in a density of at least 10^4 colony-forming units (CFUs) per milliliter represents true infection.[16] The finding of at least one organism per high-power field on Gram stain of sinus secretions correlates with the recovery of bacteria in a density of 10^5 CFU/mL.

Microbiology

Data on the microbiology of sinusitis in pediatric patients are best organized according to the duration of clinical symptoms (Table 32.2). However, the literature review is complicated by various definitions of acute, subacute, and chronic sinusitis.

TABLE 32.2

Bacteriology of Sinusitis

Bacterial Species	Acute (10–29 Days)	Subacute (30–120 Days)	Chronic (>120 Days)
Streptococcus pneumoniae	++	++	+
Haemophilus influenzae	+++	++	+
Moraxella catarrhalis	++	++	+
Staphylococcus aureus	—	—	+
Anaerobic bacteria[a]	—	—	+

[a] Respiratory anaerobic cocci, *Bacteroides* spp., *Prevotella* spp., *Veillonella* spp.

+++, Most common; ++, common; +, less common.

Several studies of ambulatory patients with acute (i.e., 10–30 days' duration) and subacute (i.e., 30–120 days' duration)[17,18] illnesses have found the important bacterial pathogens to be *Streptococcus pneumoniae, Haemophilus influenzae,* and *Moraxella catarrhalis.* Historically, *S. pneumoniae* has been most common in all age groups, accounting for 30% to 40% of isolates. *H. influenzae* and *M. catarrhalis* have similar prevalences, and each accounts for approximately 20% of cases. In the past decade, the prevalence of penicillin-resistant *S. pneumoniae* has depended on the use of conjugate pneumococcal vaccine and emergence of nonvaccine serotypes. Many of the *H. influenzae* (35% to 50%) and *M. catarrhalis* (55% to 100%) organisms produce β-lactamase and are resistant to penicillin.[19,20] Less frequently recovered bacteria are group A streptococci, group C streptococci, viridans streptococci, *Peptostreptococcus* spp., other *Moraxella* spp., and *Eikenella corrodens.*[16] Neither staphylococci nor anaerobic respiratory flora are recovered commonly from patients with acute or subacute sinusitis.

Respiratory viruses, including adenovirus, parainfluenza virus, influenza virus, and rhinovirus, are identified with or without bacterial species in approximately 10% of patients. The percentage would almost certainly be higher if nasal samples were obtained earlier in the course of respiratory symptoms.

No data regarding the microbiology of ABS in children have been generated since 1984.[21] However, because of the similarity of the pathogenesis and microbiology of acute otitis media and ABS, data from cultures of middle ear fluid obtained by tympanocentesis from children with acute otitis media have been used as a surrogate for cultures of the paranasal sinuses.[22] After 2000, heptavalent pneumococcal conjugate vaccine (PCV7) was used in the United States, and several reports in 2004 highlighted a decrease in isolates of *S. pneumoniae* and an increase in isolates of *H. influenzae* recovered from middle ear aspirates.[23,24] The change in microbiology reflects the decrease in recovery of vaccine strains of *S. pneumoniae* from the nasopharynx.[19] However, after several years, the emergence of nonvaccine strains of *S. pneumoniae* restored temporarily the relative proportions of *S. pneumoniae* and *H. influenzae* to those observed before 2000.[20,25]

Licensure of PCV13 in 2010 again decreased the recovery of *S. pneumoniae* from children with acute otitis media and presumably from children with ABS. In a 2014 publication, 36% of middle ear isolates were *H. influenzae*, and 29% were *S. pneumoniae*.[26] Diminishing sources of information regarding the microbiology of acute otitis media and ABS are a challenge.

In patients with very protracted (i.e., years) or severe sinus symptoms (i.e., requiring surgical intervention), *S. aureus* and anaerobic organisms are recovered more frequently. Commonly recovered anaerobic bacteria are gram-positive cocci (e.g., *Peptococcus* spp., *Peptostreptococcus* spp.) and *Bacteroides* or *Prevotella* spp.[27] Viridans streptococci and *H. influenzae* also are recovered frequently.

Medical Management

Acute Sinusitis

Antimicrobial agents are mainstays in the medical management of sinusitis.[7,9] Table 32.3 shows a list of agents potentially useful in patients with ABS. Amoxicillin has been the treatment of choice for many cases of uncomplicated sinusitis in children. It is effective most of the time, has a narrow spectrum, and is inexpensive and safe. Concern about penicillin-resistant *S. pneumoniae* should prompt the use of high-dose amoxicillin (90 mg/kg/day).[7] Resistance due to alteration of the penicillin-binding proteins can be overcome for the most part with high-dose amoxicillin. However, amoxicillin at any dose does not cover β-lactamase–producing *H. influenzae* and *M. catarrhalis*. Amoxicillin, if used at all, should be reserved for children with mild illness early in the respiratory season who have no risk factors for infection with resistant bacterial species.

TABLE 32.3

Antimicrobial Agents and Dosage Schedules for the Treatment of Sinusitis in Children

Antimicrobial Agent	**Dosage**
Amoxicillin	45–90 mg/kg/day in 2 divided doses
Amoxicillin/potassium clavulanate	45/10 mg/kg/day in 2 divided doses
Amoxicillin/potassium clavulanate (high dose)	90/6.4 mg/kg/day in 2 divided doses
Cefpodoxime proxetil	10 mg/kg once daily
Cefuroxime axetil	30 mg/kg/day in 2 divided doses
Cefdinir	14 mg/kg/day in 1 or 2 daily doses
Cefprozil	30 mg/kg/day in 2 divided doses

A broader-spectrum regimen is appropriate in the following clinical situations: lack of symptom improvement with amoxicillin therapy in 48 to 72 hours, any risk factors for resistant bacterial species (e.g., young age, attendance at childcare, recent treatment of the index case or a close contact with an antibiotic), frontal or sphenoidal sinusitis, complicated ethmoidal sinusitis (i.e., with even minimal eye swelling), and protracted (>30 days) symptoms. Antimicrobial agents with the most comprehensive coverage for patients with sinusitis are high-dose amoxicillin with potassium clavulanate (90 mg/kg/day of amoxicillin and 6.4 mg/kg/day of clavulanate in 2 divided doses; maximal dose of 8 g/day of amoxicillin), cefuroxime axetil (30 mg/kg in 2 divided doses), and cefpodoxime proxetil (10 mg/kg once daily). For patients with chronic sinusitis, amoxicillin with potassium clavulanate is an attractive choice, especially because the mode of amoxicillin resistance in the pathogens causing chronic sinusitis is β-lactamase production.

Other antimicrobial agents that are available for the management of respiratory infections but are considerably less potent or adequate in spectrum are cefdinir, cefprozil, clarithromycin, and azithromycin. Clarithromycin and azithromycin should be reserved for children who have lower respiratory tract disease suggesting

Mycoplasma infection or have a type 1 hypersensitivity reaction to β-lactam agents. Neither agent is effective against *H. influenzae*.

Infections due to penicillin-resistant pneumococci are a persistent problem. Organisms are classified as *susceptible* when the minimum inhibitory concentration (MIC) of the drug is less than 0.1 μg/mL, *moderately resistant* when the MIC is between 0.1 and 1.0 μg/mL, and *resistant* when the MIC is more than 1 μg/mL for oral β-lactams. The frequency of penicillin-resistant pneumococci varies geographically, and many isolates of pneumococci are resistant to other commonly used antimicrobial agents, such as trimethoprim-sulfamethoxazole, erythromycin-sulfisoxazole, clindamycin, and the macrolides azithromycin and clarithromycin. Therapeutic options include high-dose amoxicillin, an advanced-generation cephalosporin (for some pneumococci with moderate resistance), linezolid, and rifampin. Selection of an antimicrobial agent should be guided by susceptibility test results when available.

Patients with ABS may require hospitalization because of systemic toxicity or an inability to take antibiotics orally. These patients can be treated with intravenous ceftazidime (150 mg/kg/day in 3 divided doses), intravenous ceftriaxone (100 mg/kg/day given once daily), or intravenous ampicillin-sulbactam (200 mg/kg/day of the ampicillin component in 4 divided doses [not approved for children younger than 12 years]).

Clinical improvement is prompt in almost all children treated with an appropriate antimicrobial agent, with a remarkable reduction in 48 to 72 hours of fever, nasal discharge, and cough. If symptoms do not improve or worsen in 48 to 72 hours, clinical re-evaluation is appropriate. If amoxicillin was prescribed initially, an antimicrobial agent effective against β-lactamase–producing bacterial species and penicillin-resistant pneumococci should be prescribed. If amoxicillin-clavulanate was prescribed originally and the patient has not improved, cefpodoxime, cefuroxime, or a combination of linezolid and cefixime are reasonable second-line therapies. Levofloxacin may be considered for patients with a type I hypersensitivity reaction to amoxicillin. If the patient still has not improved, parenteral therapy and sinus aspiration for precise bacteriologic identification should be considered.

The appropriate duration of antimicrobial therapy for patients with ABS has not been investigated systematically. For patients whose respiratory symptoms improve dramatically within 3 to 4 days of commencement of therapy, 10 days of treatment is adequate. For cases that respond more slowly, it is reasonable to treat until the patient is symptom free plus an additional 7 days.

Adjuvant therapies such as antihistamines, decongestants, and nasal irrigation have received little systematic evaluation. There is no evidence to demonstrate whether the use of these modalities is efficacious in children with acute sinusitis.[28]

Chronic Sinusitis

Some children experience recurrent or chronic episodes of sinusitis. The most common cause of recurrent sinusitis is a recurrent viral URI, which often is a consequence of attendance at out-of-home childcare or the presence of a school-aged child in the household. Other conditions predisposing to sinus ostial obstruction should be considered (see Table 32.1). Evaluation of children with recurrent or chronic sinusitis should include consideration of consultation with an allergist, performance of a sweat test, quantitative measurements of serum immunoglobulin levels, and a mucosal biopsy to assess ciliary structure and function.

If specific allergens are identified or an allergic diathesis is documented, therapy may include desensitization, an antihistamine, or topical intranasal steroid therapy. If a treatable immunodeficiency is identified, specific immunoglobulin therapy is initiated. Antimicrobial prophylaxis has not been studied in patients with recurrent acute sinusitis, although it has proved to be a useful strategy in reducing symptomatic episodes of acute otitis media in patients with frequent recurrences. Recent concerns regarding antibiotic resistance have discouraged the use of antibiotic prophylaxis. If sinusitis does not respond to maximal medical therapy, surgical intervention may be appropriate.

The major complications of acute sinusitis are shown in Box 32.2. Subperiosteal abscess of the orbit and intracranial abscess (i.e., subdural and epidural empyema) are the most common.[29,30] Signs of orbital infection are eyelid swelling, proptosis, and impaired extraocular eye movements. With intracranial spread of infection, there may be signs of increased intracranial pressure, meningeal irritation, and focal neurologic signs. CT or MRI is essential for diagnosis. Antibiotic therapy and surgical drainage usually are required for successful treatment. For small subperiosteal abscesses unaccompanied by visual loss, a trial of antibiotic therapy alone is appropriate.

Box 32.2

Major Complications of Sinusitis

Orbital

Inflammatory edema[a]

Subperiosteal abscess

Orbital abscess

Orbital cellulitis

Optic neuritis

Intracranial

Epidural empyema

Subdural empyema

Cavernous or sagittal sinus thrombosis

Meningitis

Brain abscess

Osteitis

Frontal (Pott puffy tumor)

---

[a] Inflammatory edema is not a true orbital complication of sinusitis. Infection is confined to the paranasal sinuses, and periorbital swelling results from impedance of venous blood flow.

Surgical Management

Patients with acute sinusitis rarely require surgical intervention in the absence of orbital or central nervous system complications. An appreciation of allergic rhinitis or other underlying medical problems such as gastroesophageal reflux in chronic sinusitis has led to more aggressive medical management and less enthusiasm for surgical solutions.[31] Occasionally, sinus aspiration is required to ventilate a sinus in a patient with no response to aggressive antimicrobial therapy.

In the rare child who has failed conventional treatment with oral antibiotics and an array of local and systemic adjuvants to therapy, a trial of antibiotic therapy delivered by a percutaneous intravenous catheter may be worthwhile.[32] It can be combined with adenoidectomy, or adenoidectomy can be undertaken as a solo intervention. Adenoidectomy is considered first-line surgical therapy for chronic rhinosinusitis in childhood,[33,34] although the success of the procedure correlates with associated conditions such as adenoiditis and asthma.[35]

When functional endoscopic sinus surgery is performed, the focus is on the ostiomeatal complex (Fig. 32.3). This area between the middle and inferior turbinates represents the confluence of drainage areas of the frontal, ethmoid, and maxillary sinuses, and it is predisposed to local impairment of mucociliary clearance. Using an endoscope, the natural meatus of the maxillary outflow tract is enlarged by excising the uncinate process and the ethmoid bullae and performing an anterior ethmoidectomy.

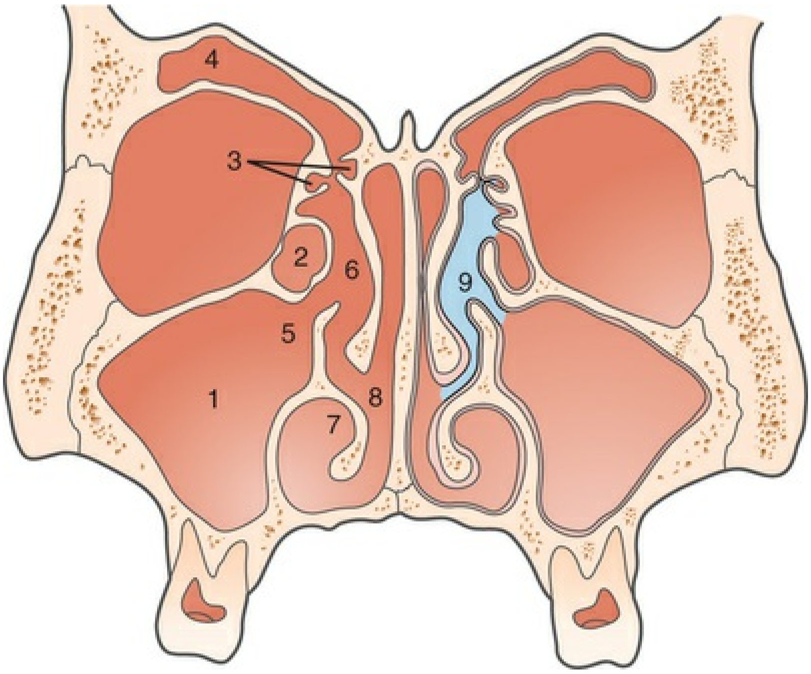

FIGURE 32.3 Coronal section of the nose and paranasal sinuses: *1*, maxillary sinus; *2*, ethmoidal bursa; *3*, ethmoid cells; *4*, frontal sinus; *5*, uncinate process; *6*, middle turbinate; *7*, inferior turbinate; *8*, nasal septum; *9*, ostiomeatal complex *(blue area)*. (From Wald ER. Sinusitis in children. N Engl J Med 1992;326:319–323.)

As understanding of the pathogenetic factors predisposing to sinusitis expands and therapy for these mucosal diseases becomes more effective, the pediatric candidates for surgical management of sinus disease will continue to decrease. Judicious use of surgery in young children with chronic rhinosinusitis is strongly recommended.[36]

Lower Respiratory Tract Infections

OUTLINE

33 Bronchiolitis
34 Acute Pneumonia and Its Complications
35 Persistent and Recurrent Pneumonia
36 Pneumonia in the Immunocompromised Host

33

Bronchiolitis

H. Cody Meissner

Bronchiolitis is a syndrome of inflammation and obstruction of the lower respiratory tract that usually is caused by a viral infection occurring in the first 12 months of life.[1] Between 2% and 3% of infants younger than 1 year of age are hospitalized with bronchiolitis annually, accounting for 57,000 to 175,000 hospitalizations in the United States.[2–4]

Yearly hospital admissions attributable to bronchiolitis increased more than twofold between 1980 and 1996, likely reflecting the increased use of childcare centers and changes in criteria for hospital admission for children with bronchiolitis.[5] However, during the first 16 years of the 21st century, bronchiolitis hospitalization rates have fallen by 20% to approximately 20 to 30 admissions per 1000 children younger than 12 months of age.[6] One explanation for lower rates of bronchiolitis hospitalization is the improved health of neonates at the time of discharge compared with several years earlier. This can be attributed to the use of antenatal glucocorticoids, surfactant replacement, improvements in methods for ventilatory support, corrective cardiac surgery performed earlier in life, and a better understanding of neonatal nutrition.

Etiologic Agents

During seasonal outbreaks of bronchiolitis from November through March in North America, respiratory syncytial virus (RSV) is identified as the etiologic agent in up to 80% of hospitalized children[7] (Table 33.1). Other respiratory viruses that cause a largely indistinguishable syndrome include human rhinoviruses, parainfluenza viruses, human metapneumoviruses, coronaviruses, adenoviruses, influenza viruses, enteroviruses, and human bocaviruses.[8–11] The yearly cycles of respiratory virus circulation are depicted in Fig. 33.1.

TABLE 33.1

Infectious Causes of Bronchiolitis

Infectious Agent	**Occurrence**[a]
Respiratory syncytial virus	++++
Rhinovirus	++
Human metapneumovirus	++
Parainfluenza virus 3	++
Parainfluenza virus 1	+
Parainfluenza virus 2	+
Coronaviruses	+
Adenovirus	+
Influenza virus (A or B)	+
Mycoplasma pneumoniae	+
Enterovirus	+

[a] Relative importance varies with season and epidemic disease.

++++, Most common cause; ++, causes substantial percentage of cases in some studies; +, occasional cause.

Data from references 7, 8, 39–41.

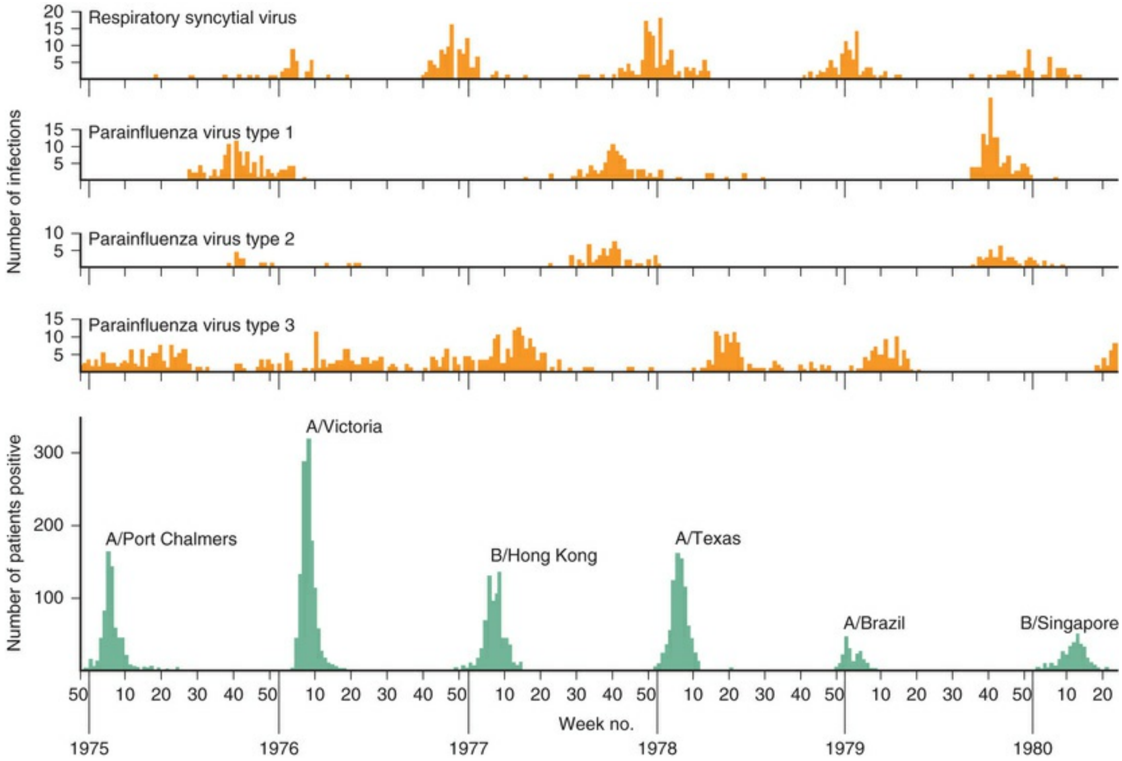

FIGURE 33.1 Patterns of occurrence of respiratory syncytial virus and parainfluenza virus in Houston, Texas. (From Couch RB. Viral respiratory diseases. In: Stringfellow DA [ed]. Virology. Kalamazoo, MI: Scope; 1983, p. 65.)

No evidence has been found for a primary role for bacteria as a cause of bronchiolitis. However, *Bordetella pertussis, Chlamydia trachomatis,* and *Mycoplasma pneumoniae* should be included in the differential diagnosis of a young child with lower respiratory tract infection.

Epidemiology

The peak incidence of severe disease occurs before 6 months of age, and the highest rates of hospitalization occur among infants between 60 and 90 days of age.[1] Most of those hospitalized for bronchiolitis are term infants with no known risk factors. Chronologic age is the single most important determinant for severe bronchiolitis; about two thirds of hospitalizations occur before 6 months of age.[1,2] Several reasons may account for this age distribution. Birth shortly before or soon after the onset of the RSV season results in a longer period of exposure to RSV earlier in life. Maternal antibody concentrations to RSV also show seasonal variation, and infants born early in the RSV season are more likely to be born to mothers with low neutralizing antibody concentrations.[12–14]

Certain comorbidities, including prematurity (<29 weeks' gestation), chronic lung disease of prematurity, and hemodynamically significant congenital heart disease, may result in more severe disease compared with children without these comorbities.[15,16] Worldwide, 65,000 to 200,000 deaths due to bronchiolitis were estimated to occur in 2005 among children younger than 5 years of age.[17,18] Fewer than 100 US pediatric deaths occur annually as a complication of RSV-associated bronchiolitis.[19]

Occurrence of the respiratory virus season is predictable even though the severity of the season, the date of onset, the peak of activity, and the end of the season cannot be predicted with precision.[20] There can be variation in timing of community outbreaks of disease due to RSV from year to year in the same community and among neighboring communities, even in the same season. Southern US communities tend to experience the earliest onset of RSV activity, and those in the Midwest tend to experience the latest onset. The duration of the season in western and northeastern areas is typically between that in the South and the Midwest. Nevertheless, these variations occur within the overall pattern of RSV outbreaks, usually beginning in November or December, peaking in January or February, and ending by the end of March or April.[20–23]

Limited numbers of cases of bronchiolitis may occur during late spring, summer, and early fall, and they often are caused by viruses other than RSV, such as rhinoviruses or parainfluenza viruses. These cases often are milder than RSV-related cases. In tropical countries, the annual epidemic of RSV coincides with the rainy season, although cases can occur throughout the year.

Household crowding is a risk factor for severe viral lower respiratory tract illness due to RSV and other respiratory viruses.[24–27] As the number of household members increases, the likelihood of close exposure to infectious respiratory secretions also increases. Childcare attendance has been correlated with an increased risk of bronchiolitis in some studies.

Unlike other respiratory viral infections, exposure to passive household tobacco smoke has not been associated with an increased risk of RSV hospitalization on a consistent basis. Exposure to secondhand smoke has been associated with an increased risk of respiratory infections due to other viruses. In contrast to the well-documented benefit of breastfeeding against some viral illnesses, existing data are conflicting regarding the specific protective effect of breastfeeding against RSV infection.

Other reported risk factors for bronchiolitis include poverty, malnutrition, maternal smoking during pregnancy, congenital malformation of the airways, neuromuscular impairment, household crowding, childcare attendance, size of the childcare facility, lower level of maternal education, and living at an increased altitude. However, most of these risk factors are inconsistent from study to study, and in most instances, the impact on increased hospitalization is small.[15]

Pathogenesis and Pathologic Findings

Acute bronchiolitis is caused by an infectious agent, usually a respiratory virus with specific tropism for bronchiolar epithelium. Because most infants experience mild illness and recover from bronchiolitis, information regarding the pathologic changes caused by infection is not available.

Largely based on results from animal studies, RSV infection of the epithelial cells of the human respiratory tract mucosa results in a lymphocytic infiltration of the bronchiolar walls and edema of the surrounding tissue. Disease progression is associated with proliferation and necrosis of the bronchiolar epithelium. The sloughed necrotic epithelium and the increased mucus production lead to obstruction of the lumen of the infant's small airways. Air movement is restricted during inspiration and expiration but is more restricted during expiration, when the lumen is further compromised by positive expiratory pressure, resulting in expiratory wheezing. Obstruction results in air trapping and the characteristic appearance of hyperinflation on chest radiographs. As this air is absorbed, the radiographic pattern evolves to show atelectasis.[23,27–29] Chapter 225 discusses the pathophysiology of RSV bronchiolitis.

Clinical Manifestations

Upper respiratory tract symptoms consisting of nasal congestion and discharge and a low-grade fever begin about 3 to 5 days after the onset of infection. Bronchiolitis represents the later stage of a respiratory viral infection that develops after 2 to 4 days of illness. Approximately 30% to 40% of RSV-infected infants experience progression of disease to the lower respiratory tract. Spread to the lower airway occurs by aspiration of sloughed RSV-infected epithelial cells from the upper airway or by cell-to-cell spread of the virus.

Lower airway involvement is marked by an increase in the work of breathing, cough, tachypnea, wheezing, crackles, use of accessory muscles, and nasal flaring.[1] The respiratory rate often exceeds 60 to 70 breaths/min in young infants. Intercostal, supracostal, and subcostal retractions are evident. Initially, wheezing occurs during the expiratory phase only and is audible only through a stethoscope. As wheezing progresses, it can be heard without a stethoscope. The chest becomes hyperexpanded and hyperresonant, respirations become more labored, and retractions become more severe. Mild hypoxemia occurs in most infants with bronchiolitis. Respiratory failure can occur due to progressive hypercapnia and respiratory muscle fatigue.[1]

Disease severity may be recognized by the absence of audible air exchange on auscultation; flaring of the alae nasi; expiratory grunting; severe subcostal, supraclavicular, and intercostal retractions; and hypoxemia. A child with these findings may require intubation and ventilatory support. Apnea can be an early manifestation of RSV infection, sometimes resulting in respiratory failure.[30–32] Because the severity of bronchiolitis often waxes and wanes before consistent improvement, serial assessment of respiratory status should be performed. The ability of a young infant to breastfeed or bottle-feed without distress over time often provides a practical guide to disease severity and management. An infant who has substantial difficulty feeding as a result of respiratory distress has moderate or severe illness and usually requires hospitalization.

Otherwise healthy infants younger than 2 months of age, infants born prematurely (<29 weeks′ gestation), and infants with chronic lung disease of prematurity or infants born with congenital heart disease are most likely to experience severe RSV disease.[1] Infants born with hemodynamically significant congenital heart disease are at increased risk of more severe bronchiolitis.[15,16,33,34] Infants with hemodynamically insignificant heart disease, including secundum atrial septal defect, small ventricular septal defect, pulmonic stenosis, uncomplicated aortic stenosis, mild coarctation of the aorta, and patent ductus arteriosus, and infants with lesions adequately corrected by surgery (unless they continue to require medication for management of congestive heart failure) are not considered to be at increased risk for hospitalization.[35] Severe respiratory distress with bronchiolitis can be the presenting manifestation of previously unrecognized congenital heart disease.

RSV-infected infants have various courses after hospitalization.[22] Among otherwise healthy infants, intensive care unit admission because of respiratory deterioration is uncommon (approximately 2% of patients). The decision to admit to the intensive care unit is based on the possible need for intubation because of progressive hypercapnia, increasing hypoxemia despite supplemental oxygen, or episodes of apnea.

The typical course for a previously healthy infant older than 6 months of age is one of improvement over 2 to 3 days, as evidenced by a lower respiratory rate and fewer retractions. Pulmonary function abnormalities and evidence of mild desaturation may persist for several weeks. The differential diagnosis of bronchiolitis includes airway hypersensitivity to environmental irritants, anatomic abnormality of the airway, cardiac disease with pulmonary edema, cystic fibrosis, foreign-body aspiration, and gastroesophageal reflux.

Diagnosis

A diagnosis of bronchiolitis should be based on the history and physical examination. Serial examinations may reveal fluctuations in disease acuity over a short period, reflecting rapid changes in blockage of the lumens of the small airways.[1] Specific signs and symptoms at the time of presentation have a limited ability to predict disease severity. Assessment of the likelihood of progressive disease should consider the risk factors, including: age younger than 12 weeks, a history of prematurity, underlying cardiopulmonary disease, or immunodeficiency.[1]

Routine radiographic studies are not recommended. Infants with bronchiolitis may have abnormalities (e.g., atelectasis) on chest radiography, but the changes have little correlation with disease severity.[36,37] Radiography should be reserved for infants who require intensive care management and for those who do not improve as expected.

Routine virologic testing is not recommended because the result is unlikely to influence management.[1] Respiratory isolation recommendations are similar for most viral infections and are based largely on the symptoms, not the specific cause. The positive predictive value of an antigen detection assay decreases as disease incidence goes down. Specificity of antigen detection assays is lowest during the off-season and at the onset and the end of the respiratory virus season.

Polymerase chain reaction (PCR) assays have improved sensitivity and specificity compared with antigen detection, but they are expensive, and results are unlikely to influence management. Using PCR assays, coinfections with more than one virus have been identified in as many as one third of hospitalized patients with bronchiolitis. The significance of coinfections is incompletely understood.[38–42] PCR assays should be interpreted with caution because positive results can be found in more than 30% of asymptomatic young children.[43] Whether this reflects prolonged shedding from a previous infection, the incubation period for a pending infection, infection by a strain with limited ability to cause disease, or a low-grade infection producing small amounts of virus is unknown.

Management

General Measures

Most infants with bronchiolitis can be managed at home with supportive care, but concerns regarding increasing respiratory effort, apnea, or inability to feed adequately may precipitate hospitalization of a young child.[1] Disease severity may be estimated by respiratory rate, use of accessory muscles, and degree of hypoxemia. However, the course of bronchiolitis varies, ranging from mild dyspnea to progressive respiratory distress. Certain underlying conditions such as prematurity, immunodeficiency, chronic lung disease of prematurity, and congenital heart disease are associated with an increased risk of progression to severe disease.

Despite the high burden of disease from bronchiolitis, no available treatment shortens the course or hastens the resolution of symptoms. Therapy is supportive, and most children with bronchiolitis do well regardless of management.[1]

Therapies

Bronchodilator Therapy.

Most randomized, controlled trials have failed to demonstrate a consistent benefit from α- or β-adrenergic agents. Although transient improvement in respiratory status has been reported, most infants treated with bronchodilators do not benefit from their use.[44–47] The potential adverse effects (i.e., tachycardia and tremors) and cost of these agents outweigh the potential benefits. Recommendations from the American Academy of Pediatrics state, "Clinicians should not administer albuterol to infants and children with a diagnosis of bronchiolitis."[1]

Epinephrine.

Epinephrine is an adrenergic agent with α- and β-receptor agonist activity. It has been evaluated in children with bronchiolitis after systemic administration and when delivered directly into the respiratory tract. Large, multicenter trials comparing nebulized epinephrine with albuterol or placebo in hospitalized children with bronchiolitis found no improvement in outcomes.[48–50] Available evidence does not support a role for epinephrine use among hospitalized patients or outpatients with bronchiolitis.

Corticosteroid Therapy.

Although corticosteroids may benefit selected patients with asthma or croup, no evidence supports the use of corticosteroid therapy in the general population of children with bronchiolitis. Numerous studies have documented a lack of benefit.[51–53]

Oxygen Therapy.

Various degrees of hypoxia are commonly seen in infants and young children with bronchiolitis. Intermittent periods of hypoxemia (≥90% oxyhemoglobin saturation) as measured by pulse oximetry should not be interpreted as a need for supplemental oxygen. Transient desaturation is common in healthy infants. Oxygen saturation has much less impact on respiratory drive than carbon dioxide concentration in the blood. Oxygen saturation and respiratory distress have poor correlation among infants with lower respiratory tract infections. Continuous monitoring with pulse oximetry of children with mild degrees of oxygen desaturation has been associated with prolonged length of stay compared with children who do undergo continuous monitoring.[54,55]

Chest Physiotherapy.

Suctioning of the nasopharynx to remove secretions and temporarily improve airflow is a common practice for children with bronchiolitis. Chest physiotherapy using vibration or percussion or deep suctioning is not recommended.[56,57]

Hydration.

As many as one third of patients admitted to the hospital with a diagnosis of bronchiolitis require fluid replacement therapy. The ability to swallow may be compromised when the respiratory rate exceeds 60 breaths/min, especially if the child has nasal congestion. For infants who are unable to maintain hydration orally, fluid may be administered intravenously or through a nasogastric tube.[58,59]

Antibiotic Therapy.

Antibacterial therapy should not be administered to an infant or young child with bronchiolitis unless there is a strong suspicion of a concomitant bacterial infection.[1]

Nebulized Hypertonic Saline.

Data suggest that nebulized hypertonic saline may have a modest benefit in infants with RSV bronchiolitis.[60–62] Hypertonic saline may facilitate mucociliary clearance of the bronchioles that results from the inflammatory response to infection. Some evidence suggests that 3% inhaled saline may be safe and may reduce length of hospital stay when a hospitalization lasts longer than 3 days.

Antiviral Therapy.

Ribavirin is a nucleoside analogue with in vitro activity against RSV, adenovirus, influenza A and B viruses, and parainfluenza viruses. Early trials indicated that ribavirin therapy was associated with a modest improvement in clinical scores, oxygenation, and duration of mechanical ventilation for infants with severe bronchiolitis due to RSV infection. These studies were challenged on the basis that control groups received water aerosols, which can produce bronchospasm in individuals with hyperreactive airways. Clinical trials with ribavirin have not demonstrated a consistent decrease in the need for mechanical ventilation, decrease in length of stay in the intensive care unit, or reduction in days of hospitalization. Conflicting results from efficacy trials, concern about the potential toxic effects among exposed healthcare professionals, aerosol route of administration, and high cost have resulted in the limited use of ribavirin.[63]

Chapter 225 discusses ribavirin. Options for the treatment of bronchiolitis if caused by influenza A or B viruses are discussed in Chapter 229.

Prognosis, Complications, and Sequelae

Most infants recover completely from acute bronchiolitis. Severe bronchiolitis early in life is associated with an increased risk of asthma, especially after RSV or rhinovirus bronchiolitis, and the risk can persist into early adulthood. It is not understood whether bronchiolitis injures the lung such that normal lung development does not occur and predisposes to subsequent episodes of wheezing or whether certain infants have a pre-existing aberration of the immune response or airway function that predisposes to severe bronchiolitis and recurrent wheezing.[64–69]

Prevention

Strategies that reduce exposure of vulnerable infants to contagious individuals with respiratory tract infections offer opportunities to reduce bronchiolitis morbidity. Encouraging breastfeeding and avoiding passive exposure to cigarette smoke are critical aspects of proper healthcare for all children. The role of monoclonal antibodies in reducing the risk of RSV infection in certain high-risk infants and young children is discussed in Chapter 225.

No safe and effective vaccine is available to prevent infection with RSV or most other viral causes of bronchiolitis. The influenza vaccine is the only exception, and this vaccine should be administered annually to all infants starting at 6 months of age. Because influenza vaccine is not approved for use in infants younger than 6 months of age, annual influenza vaccination is important for the family members and caregivers of young patients.

Acute Pneumonia and Its Complications

Chitra S. Mani

Pneumonia is a Greek word meaning “inflammation of the lungs.” It is the most common cause of morbidity and mortality in infants and children due to infection worldwide.[1]

Acute Pneumonia

Pneumonia is a lower respiratory tract disease usually caused by an infectious agent resulting in inflammation of the tissues of one or both lungs.[2] Pneumonia in developing countries occurs in >150 million new cases and results in >1.3 million preventable deaths each year.[1,3] Morbidity and mortality rates for community-acquired pneumonia (CAP) among the children in the United States is considerably less. Outpatient pediatric visit rates for CAP in the US ranges from 16.9 to 22.4 per 1000 children, with 32.3 to 49.6 cases per 1000 children 1 to 5 years of age.[4] Rate of hospitalization in the US for acute pneumonia decreased from 12–14 to 8–10 per 10,000 in children <2 years of age following universal conjugate pneumococcal vaccination.[5] In 2007, the overall mortality for acute pneumonia in US children was ≤2%, depending on factors including age, race, socioeconomic status and geographical region.[6]

Epidemiology

In the US, lower respiratory infections (LRIs) occur throughout the year but excessively during the fall and winter when children are confined indoors, resulting in more efficient spread of the infections by contact or droplet transmission.[7] Multiple factors predispose to acquisition of LRI: daycare and school attendance, indoor crowding, passive exposure to smoke, lack of or underimmunization, alcohol abuse in adolescents causing aspiration pneumonia, and underlying medical conditions such as low birth weight, bronchopulmonary dysplasia, asthma, heart disease, seizures, neuromuscular illness, gastroesophageal reflux disease, malnutrition, immunocompromised state, sickle cell disease, and cystic fibrosis.[1,8–10] Additional risk factors associated with pneumonia in children <5 years of age include frequent upper respiratory tract infections (URIs; >3 episodes in 12 months), wheezing at any age, and history of otitis media requiring tympanocentesis before 2 years of age. Risk factors for pneumonia in children >5 years of age include wheezing at any age and ≥3 episodes of URI within 12 months.[11]

Etiologic Agents

Multiple microbes, most predominantly viruses and bacteria, cause LRI in infants and children. The true prevalence of the pathogens causing LRI is uncertain because microbial etiology is ascertained infrequently, owing to difficulty in differentiating infection from colonization and lack of dependable diagnostic laboratory tests.[12] In two studies of immunocompetent children with pneumonia, specific etiologic agents were confirmed in only 43% to 66%.[13,14] Some cases have more than one pathogen identified, making assigning etiology difficult.[15] Confirming etiology of bacterial pneumonia is challenging because of coexistence of bacteria as pathogens as well as normal upper respiratory tract flora, and because of occurrence of bacteremia in only 1% to 10% of hospitalized children with presumed bacterial pneumonia.[2,16,17] Etiologic agents causing pneumonia vary by age, underlying illnesses, maturity, and condition of the immune system.[18] In most cases of acute pneumonia, extensive invasive testing is not warranted. Epidemiologic information frequently is useful in guiding differential diagnosis and management (see Chapter 21). Certain pathogens, particularly respiratory syncytial virus (RSV), rhinoviruses, influenza viruses, and *Mycoplasma,* are seasonal. In other instances, the pattern of family illness provides a clue to the causative nonbacterial agents.

For purposes of management, the relative importance of etiologic agents in a series of patients who have been extensively evaluated is extrapolated to patients with similar clinical syndromes, physical findings, and laboratory results. Table 34.1 lists the common etiologic agents of acute pneumonia in children.

TABLE 34.1

Microbial Causes of Community-Acquired Pneumonia in Childhood

Age	Etiologic Agents[a]	Clinical Features
Birth–3 wk	Group B *Streptococcus*	Part of early-onset septicemia; usually severe
	Gram-negative enteric bacilli	Frequently nosocomial; occurs infrequently within 1 week of birth
	Cytomegalovirus	Part of systemic cytomegalovirus infection
	Listeria monocytogenes	Part of early-onset septicemia
	Herpes simplex virus	Part of disseminated infection
	Treponema pallidum	Part of congenital syndrome
	Genital *Mycoplasma* or *Ureaplasma*	From maternal genital infection; afebrile pneumonia
3 wk–3 mo	*Chlamydia trachomatis*	From maternal genital infection; afebrile, subacute, interstitial pneumonia
	Respiratory syncytial virus (RSV)	Peak incidence at 2–7 months of age; usually wheezing illness (bronchiolitis/pneumonia)
	Parainfluenza viruses (PIV), especially type 3	Similar to RSV, but in slightly older infants and not epidemic in the winter
	Streptococcus pneumoniae	The most common cause of bacterial pneumonia
	Bordetella pertussis	Primarily causes bronchitis; secondary bacterial pneumonia and pulmonary hypertension can complicate severe cases
3 mo–5 yr	RSV, PIV, influenza, hMPV, adenovirus, rhinovirus	Most common causes of pneumonia
	Streptococcus pneumoniae	Most likely cause of lobar pneumonia; incidence may be decreasing after vaccine use
	Haemophilus influenzae	Type b uncommon with vaccine use; nontypable stains cause pneumonia in immunocompromised hosts and in developing countries
	Staphylococcus aureus	Uncommon, although CA-MRSA is becoming more prevalent
	Mycoplasma pneumoniae	Causes pneumonia primarily in children >4 yr

	Mycobacterium tuberculosis	Major concern in areas of high prevalence and in children with HIV
5–15 yr	*Mycoplasma pneumoniae*	Major cause of pneumonia; radiographic appearance variable
	Chlamydophila pneumoniae	Controversial, but probably an important cause in older children in this age group

[a] Ranked roughly in order of frequency. Uncommon causes with no age preference: enteroviruses (echovirus, coxsackievirus), mumps virus, Epstein-Barr virus, Hantavirus, *Neisseria meningitidis* (often group Y), anaerobic bacteria, *Klebsiella pneumoniae, Francisella tularensis, Coxiella burnetii, Chlamydia psittaci. Streptococcus pyogenes* occurs sporadically or especially associated with varicella-zoster virus infection.

CA-MRSA, community-acquired methicillin-resistant *Staphylococcus aureus;* HIV, human immunodeficiency virus; hMPV, human metapneumovirus.

Agents in Neonates and Young Infants

Pneumonia in neonates can manifest as early-onset disease (within 3 days of life) or late-onset disease (after 3 days of life). Most early-onset infections are caused by organisms acquired from the maternal genital tract through aspiration of contaminated amniotic fluid or genital tract secretions. Group B *Streptococcus* is the most frequent cause of early-onset pneumonia.[2] Early-onset infection due to group B *Streptococcus*, *Listeria monocytogenes, Escherichia coli,* and other gram-negative bacilli can cause severe respiratory distress resembling hyaline membrane disease, usually as a part of a widespread systemic infection. Prenatal and perinatal risk factors, including preterm delivery, maternal chorioamnionitis, and rupture of membranes >18 hours, increase the risk for neonatal pneumonia. Hematogenous dissemination can occur occasionally from an infected mother.

Pneumonia due to *Chlamydia trachomatis* acquired perinatally can become symptomatic 2 to 3 weeks after birth, and characteristically the infant is afebrile.[19] *Bordetella pertussis* infection in very young infants can have severe complications of apnea, bronchopneumonia, or pulmonary hypertension.[20] With wide availability of extended panels for rapid molecular diagnostic tests, viruses are increasingly confirmed as important causes of pneumonia in young infants.[21] Severe, often fatal pneumonia also can be the result of disseminated herpes simplex virus (HSV) infection in noenates.[22] Congenital cytomegalovirus (CMV) and *Treponema pallidum* are less common causes of neonatal pneumonia. Genital *Mycoplasma* and *Ureaplasma* spp. are purported causes of

LRI, especially in very low birth weight infants.[23]

Agents in Infants, Children, and Adolescents

In a recent study determining the etiologic agents for CAP in children <18 years of age, viruses accounted for 66%, bacteria for 8%, and mixed infection for 7% of cases.[7] This study also noted that viral pneumonia was more common in children <2 years of age compared with older children, whereas *Mycoplasma* was more common in children >5 years of age (19%) compared with younger children (3%).

Viruses.

Overall, viruses account for approximately 73% of CAP in childhood.[7] However, when categorized by age, viruses accounted for >80% of CAP in children <2 years compared with 49% in those >2 years of age.[7] RSV is the predominant viral pathogen of childhood pneumonia, accounting for 28%, with highest incidence in children <2 years of age.[7] Other viruses include human metapneumovirus (hMPV), parainfluenza viruses (types 1, 2, and 3), influenza viruses (A and B), adenoviruses, bocavirus, rhinoviruses, and enteroviruses. Rhinoviruses have been recovered from culture in 22% to 27% of cases of childhood pneumonia.[7] Although influenza, RSV, and hMPV are significantly associated with CAP in children, the roles of other viruses such as parainfluenza viruses, enteroviruses, rhinoviruses, coronaviruses and bocavirus are difficult to ascribe owing to dual virus detections in illness, detections in well children, and extended durations of shedding.[23a] In a case-control study, the latter viruses were negatively associated with CAP.[24] Varicella-zoster virus (VZV), CMV, and HSV typically cause LRI in immunocompromised or very young immune-naïve children. Cases of LRI due to human parechoviruses (HPeV types 1–4) have been reported, but a substantial role awaits description. LRI viral infections mirror general seasonality: RSV, hMPV, and influenza (winter), parainfluenza (spring and autumn), and rhinoviruses and adenoviruses (throughout the year).[25]

Mycoplasma pneumoniae and *Chlamydophila pneumoniae*.

LRI due to *Mycoplasma pneumoniae* affects school-aged children predominantly; molecular detection in upper respiratory secretions in younger children has less clear meaning. Coinfections with either *Streptococcus pneumoniae* (30%) or *Chlamydophila pneumoniae* (15%) occurs.[26] Infections due to *M. pneumoniae* occur in 2-to 4-year cycles.[27] Unlike respiratory viruses, transmission of *M. pneumoniae* among family members is slow, with a median interval of 3 weeks between cases.[27] Pneumonia is rarely ascribed to *C. pneumoniae* in children in the US compared with European and Asian countries and is associated with reactive airway disease or asthma in children >5 years of age. Asymptomatic carriage of *C. pneumoniae* is well documented and confounds assessment of pathogenicity.

Bacterial Pathogens.

Bacterial pneumonia is more common in children living in developing countries, related to several factors, including chronic malnutrition, crowding, inadequate vaccinations, and constant exposure to biomass fuels without adequate ventilation.[28] Various tests that determine bacterial products in blood, respiratory tract secretions, and urine have been used in an attempt to assign a causative LRI role of bacteria but are positive in <10% of cases.[7,15,29] Evidence from multiple sources indicates that *S. pneumoniae* is the single most common cause of bacterial pneumonia beyond the first few weeks of life, causing >76% of bacterial pneumonia cases.[15,16,29] Pneumococcal serotypes causing uncomplicated pneumonia in the US generally are similar to those that cause bacteremia and other invasive pneumococcal disease (IPD) or acute otitis media (see Chapter 123). In the PCV13 era, IPD, including pneumonia, occurs increasingly in older children with underlying medical condtions.[29a] Pneumococcal pneumonia occurs in all age groups, but especially in those <2 years of age.[15]

In countries with widespread immunization with the Hib conjugate vaccine, the frequency of *Haemophilus influenzae* type b (Hib) infection, including pneumonia, has plummeted.[30] Pneumonia due to non–type B and nontypable *H. influenzae* is uncommon in otherwise healthy children in the US, except in premature infants and in children with underlying chronic conditions or diseases or with hospital-associated pneumonia.[31] Acute pneumonia and necrotizing pneumonia can be caused by methicillin-susceptible *Staphylococcus aureus* (MSSA), methicillin-resistant *S. aureus* (MRSA) or community-associated MRSA (CA-MRSA), especially carrying virulence factors like Panton-Valentine leukocidin.[32] *Streptococcus pyogenes* (group A *Streptococcus*) is not a frequent cause of acute pneumonia but can cause rapidly progressive and severe pneumonia, frequently leading to hypoxemia and pleural effusion within hours. Other bacteria, especially gram-negative organisms, are rare causes of pneumonia in previously healthy children but can cause LRI in premature babies, neonates, and patients with cystic fibrosis, sickle cell disease, primary or acquired immune deficiency, or immune suppression.

Other Pathogens.

A variety of epidemiologic and host factors prompt consideration of specific organisms (Table 34.2). The most important of these is tuberculosis, which should always be suspected if there is a history of exposure, in the presence of hilar adenopathy, or when pneumonia does not respond to usual therapy. In North America and Europe, primary tuberculosis pneumonia occurs predominantly in children born to or in contact with recent immigrants from countries where tuberculosis is endemic, after contact with infected adults, or in HIV-infected children.

TABLE 34.2

Occasional Causes of Pneumonia in Special Circumstances

Organism	Risk Factors	Diagnostic Methods
Histoplasma capsulatum	Exposure in certain geographic areas (Ohio and Mississippi river valleys, Caribbean)	Culture of respiratory tract secretions; urine antigen; serum immunodiffusion antibody test; and serum *Histoplasma* complement fixation antibody test
Coccidioides immitis	Exposure in certain geographic areas (southwestern United States, Mexico, and Central America)	Culture of respiratory tract secretions; serum immunodiffusion antibody test
Blastomyces dermatitidis	Exposure in certain geographic areas (Ohio, Mississippi, St. Lawrence river valleys)	Culture of respiratory tract secretions; serum immunodiffusion antibody test
Legionella pneumophila	Exposure to contaminated water supply	Culture or direct fluorescent assay of respiratory tract secretions; antigen test on urine
Francisella tularensis	Exposure to infected animals, usually rabbits	Acute and convalescent serology
Pseudomonas	Travel to rural areas of	Culture of respiratory tract secretions; acute and

pseudomallei (melioidosis)	Southeast Asia	convalescent serology
Brucella abortus	Exposure to infected goats, cattle, or their products of conception; ingestion of unpasteurized milk	Acute and convalescent serology
Leptospira spp.	Exposure to urine of infected dogs, rats, or swine, or to water contaminated by their urine	Culture of urine; acute and convalescent serology
Chlamydia psittaci	Exposure to certain infected birds (often parakeets)	Acute and convalescent serology
Coxiella burnetii	Exposure to infected sheep	Acute and convalescent serology
Hantavirus	Exposure to dried mouse dung in a closed structure (opening cabins after winter closure)	Acute and convalescent serology; PCR test on the respiratory tract secretions

PCR, polymerase chain reaction.

Residing in or traveling to certain geographic areas raises concern for special pathogens. *Coccidioides immitis* is endemic in the southwestern US, northern Mexico, and parts of Central and South America. *Histoplasma capsulatum* is endemic in the eastern and central US and Canada. *Chlamydia psittaci* and *Coxiella burnetii* are transmitted from infected birds, animals, or humans. *Pneumocystis jirovecii* causes pneumonia in unrecognized HIV-infected infants at 3 to 6 months of age, in severely malnourished children, and in other immunocompromised or immunosuppressed hosts not receiving prophylaxis. *Legionella pneumophila* is a rare cause of pneumonia in children, affecting older or immunocompromised children after certain water-associated environmental exposures.

Pathogenesis and Pathology

Pneumonia occurs when a host susceptible to a virulent pathogen is exposed to a high-density aerosol inoculum, has a compromised systemic or secretory immunity, or has an impaired clearance mechanism.[33,34] Most patients with pneumonia have initial colonization or infection of the upper respiratory tract. Invasion of the lower respiratory tract usually occurs when normal defense mechanisms are impaired, such as associated with a viral infection, chronic malnutrition, chronic aspiration, impaired cough reflex (e.g., after sedation, neurologic damage, intubation) or after exposure to environmental pollutants. Bacterial pneumonia can occasionally occur by the hematogenous route. In the early stages of lobar or bacterial pneumonia, protein-rich edema fluid containing numerous organisms fill the alveoli, leading to marked capillary congestion and causing neutrophil exudation and intra-alveolar hemorrhage. There is decrease in lung compliance, increase in pulmonary resistance, small airway obstruction, air trapping, and change in ventilation-perfusion ratio, all leading to the clinical signs of respiratory distress.

Defense mechanisms against LRI consist of (1) anatomic and physiologic barriers; (2) humoral and cell-mediated protection; and (3) phagocytic activity. The presence of hairs in the anterior nares (that trap particles >10 μm in size), configuration of the nasal turbinates, and acute branching of airways form protective anatomic barriers. Filtration and humidification capacities of the upper airways, mucus production, and middle airway protection by the epiglottis and cough reflex (eliminating particles 2–10 μm) form physiologic barriers. The mucociliary blanket transports microscopic amounts of normally aspirated oropharyngeal flora and particulate matter up the tracheobronchial tree, minimizing the presence of bacteria below the carina. Particles <1 μm can escape into the lower airways. Immunoglobulin A (IgA) antibody is secreted into the upper airways, and IgG and IgM leach from the local capillaries into the lower airways. Alveolar fluid surfactant, fibronectin, complement, lysozyme, and iron-binding proteins also have antimicrobial activity. The lower respiratory tract has three distinct populations of macrophages: alveolar, interstitial, and intravascular macrophages. Alveolar macrophages are the preeminent phagocytic cells that ingest and kill bacteria. In addition to phagocytic function, interstitial macrophages are antigen-processing cells, whereas the intravascular macrophages clear inflammatory debris through the bloodstream. Viral infection (especially due to influenza virus), high oxygen concentration, uremia, and use of alcohol or drugs can impair function of alveolar macrophages, predisposing to pneumonia. Cell-mediated immunity plays an important role in pulmonary infections caused by viruses and intracellular organisms such as *Mycobacterium tuberculosis* and *Legionella* that survive within pulmonary macrophages.

Viral Pneumonia

Viral pulmonary infections follow three pathologic patterns: bronchiolitis, interstitial pneumonia, and parenchymal infection.

The first two patterns often overlap.[35,36] Viral pneumonia is characterized by neutrophilic infiltration of the lumen of the airway with lymphocytic infiltration of the interstitium and parenchyma of the lungs.[37] Giant cell formation and viral inclusions within the nucleus of the respiratory cells are histologically evident in many viral infections, including those caused by adenovirus, measles, varicella, CMV, and Epstein-Barr virus, especially in children with immune deficiency. Air trapping with disturbances in ventilation-perfusion ratio occur when obstructed or obliterated small airways and thickened septa impede oxygen diffusion. Necrosis of bronchial or bronchiolar epithelium occurs in severe, sometimes fatal, viral infections (e.g., adenovirus infection).

Bacterial Pneumonia

Bacterial pneumonia can follow five pathologic patterns: (1) parenchymal infection, inflammation, and consolidation of a lobe or a segment of a lobe (lobar pneumonia, the classical pattern of *S. pneumoniae*; (2) primary infection of the airways and surrounding interstitium (bronchopneumonia, often due to *S. pyogenes* and *S. aureus*); (3) necrotizing parenchymal pneumonia that occurs after aspiration of anaerobes or with certain *S. aureus* or *S. pneumoniae*; (4) caseating granulomatous disease, as due to *M. tuberculosis*; and (5) peribronchial and interstitial disease with secondary parenchymal infiltration, as can occur when viral pneumonia is complicated by bacterial infection. In bacterial pneumonia, airspaces become filled with transudates and neutrophilic exudates, impairing oxygen diffusion. The proximity of the infected alveoli to the rich pulmonary vascular bed increases the risk for bacteremia, septicemia, or shock.

Clinical Manifestations

The symptoms of pneumonia are varied and nonspecific and may be subtle depending on several factors, including the etiologic agents, age of the host, inoculum size, and individual's immune response (see Chapter 21). Acute onset of fever, rapid breathing (tachypnea), and cough are classical.[38] Fever can be absent in very young infants with *C. trachomatis*, *B. pertussis*, or *Ureaplasma* infection.[39] Infants can manifest only poor feeding and increased fussiness.[40] Children <5 years of age often have a prodrome of low-grade fever and rhinorrhea due to a viral URI before developing lower respiratory tract symptoms. Fever and rapid breathing can precede onset of cough in some children. Older children can complain of pleuritic chest pain or nuchal rigidity (each referable to lobe involvement). Signs of respiratory distress include tachypnea, hypoxemia (oxygen saturation <92%), apnea, increased work of breathing (subcostal, intercostal or suprasternal retractions; nasal flaring; or grunting) or altered mental status.[41] Guidelines developed by the World Health Organization (WHO) for the clinical diagnosis of pneumonia in developing countries highlight tachypnea and retractions as the two best indicators of LRI.[42] Tachypnea is defined as >50 breaths/min in infants <12 months, >40 for those 1 to 5 years, and >30 for children >5 years of age. Among children <5 years of age, tachypnea (as defined by WHO) had the highest sensitivity (74%) and specificity (67%) for radiologically confirmed pneumonia, but was less sensitive and specific in early disease.[38,43] Tachypnea can occur with other conditions, such as fever, asthma, cardiac disease, and metabolic acidosis. The predictive values of clinical findings for pneumonia have been studied repeatedly.[44–47] In one study, the combination of a respiratory rate >50 breaths/min, oxygen saturation <96%, and the presence of nasal flaring in children <12 months of age was highly associated with radiographically confirmed pneumonia.[40] Oxygen saturation is frequently decreased with moderate to severe pneumonia and is an indication for hospital admission.[41,48] A hypoxemic infant or child may not appear cyanotic.[49] Although hypoxemia, use of accessory muscles of respiration, head bobbing, nasal flaring, and grunting are predictive of pneumonia, their absence does not exclude pneumonia.[46,50] Decreased and bronchial breath sounds, egophony (“E” to “A” change), bronchophony, tactile fremitus, and dullness to percussion are specific signs of lung consolidation. Crackles can be absent in a dehydrated patient.[51] Isolated wheezing or prolonged expiration is associated with bronchiolitis and is uncommon in bacterial pneumonia.[44] Almost three fourths of children with radiographically confirmed pneumonia appear ill. Severity of illness correlates with the likelihood of a bacterial cause. Approximately 6% to 25% of children <5 years of age with body temperature >39°C and a white blood cell (WBC) count >20,000/mm^3 without an alternative source of major infection and with no symptoms or signs of lower respiratory tract disease have radiographically confirmed pneumonia.[47]

In one study determining the interobserver agreement of signs of pneumonia, there was more observer agreement with clinical signs (respiratory rate and cyanosis) compared with auscultatory signs (crackles, retractions, and wheezing) of pneumonia.[40] Unfortunately, neither respiratory rate nor cyanosis is a sensitive or specific indicator of hypoxia. Oxygen saturation should be measured in any child with respiratory distress.[52]

Neonates and Young Infants

The neonate with bacterial infection due to group B *Streptococcus*, *L. monocytogenes,* or gram-negative bacilli usually manifests with respiratory distress in the first few hours of life. Septicemia and infection at other sites can dominate the clinical presentation. Pneumonia in children <2 months of age usually is characterized by tachypnea (respiratory rate >60 breaths/min), intercostal retractions, or both.[52] In very young infants, particularly those who are born prematurely, fever can be absent and apneic spells can be the prominent initial finding.[53] *C. trachomatis* pneumonia in infants is insidious, with infants coming to attention at 3 to 12 weeks with staccato cough, tachypnea, and crackles in absence of fever. Wheezing is uncommon.[54] Eosinophilia and elevated total serum IgM concentration can be present.[55,56]

Infants, Children, and Adolescents

Viruses.

Viral pneumonia usually occurs in the context of a preceding upper respiratory tract illness with gradual increase in irritability, respiratory congestion, cough, posttussive emesis, and fever. The patient may not appear toxic, although hypoxia can be marked, particularly in a young infant whose initial presentation can also be apnea. The auscultatory findings are not anatomically confined, but rather there are diffuse, bilateral wheezes and crackles. Although adenovirus usually follows the pattern of other viral infections, adenovirus can cause severe pneumonia with lobar consolidation similar to a bacterial infection and is especially severe in immunocompromised hosts.[58]

Bacterial Pneumonia.

Bacterial pneumonia may follow several days of mild URI, but onset then usually is abrupt. The patient usually is ill and toxic appearing with high fever, rigors, and tachypnea. Respiratory distress and hypoxemia can be absent or mild unless there is widespread disease or a large pleural effusion. Cough occurs later in the course of the illness when alveolar debris is swept into the upper airway. Unilateral pleuritic chest pain, abdominal pain, neck pain, or sepsis in the presence of radiographically demonstrable infiltrate are specific signs of bacterial pneumonia. Unless there is a parapneumonic effusion, auscultatory findings usually are few and are limited to an anatomic lung segment.

Other Pathogens.

The major symptoms of LRI due to *M. pneumoniae, C. pneumoniae,* and *C. burnetii* (Q fever) are fever and cough that persist for more than 7 to 10 days. The onset of pneumonia caused by *M. pneumoniae* usually is not well demarcated; malaise, headache, photophobia, sore throat, fever, and chills occur early and sometimes subside when the gradually worsening, nonproductive cough ensues. Although coryza is unusual, otitis media can occur.[59] Findings on physical examination and auscultation can be minimal with confined rales, wheezing, or both.[60] The presence of Stevens-Johnson syndrome or hemolytic anemia in a patient with pneumonia suggests *M. pneumoniae* infection.[61] *M. pneumoniae* can cause severe disease in persons with sickle cell disease in whom acute chest syndrome is common.[62] Pneumonia due to *C. pneumoniae* usually has an insidious onset with sore throat, hoarseness, and associated sinusitis.[63] Pneumonia due to *C. burnetii* is rare and usually is mild in children. Symptomatic patients can have intractable headache, myalgia, arthralgia, and nonproductive cough. Chest radiograph findings include segmental or lobar consolidation; "round pneumonia" has been described with Q fever.[64]

Differential Diagnosis

Pneumonia is highly probable in children with fever, cough, tachypnea, and shortness of breath in whom chest radiograph demonstrates pulmonary infiltrates. There are many alternative diagnoses, particularly in the absence of fever, or with chronic, relapsing symptoms and signs. These include foreign-body aspiration, asthma, gastroesophageal reflux, cystic fibrosis, congestive cardiac failure, systemic vasculitis, and bronchiolitis obliterans. Children who develop chemical pneumonia after ingestion of volatile hydrocarbons can have severe necrotizing pneumonia with high fever and peripheral neutrophil counts exceeding 15,000/mm^3.[65]

Imaging and Laboratory Findings

Chest radiography often is obtained to determine whether a patient with respiratory symptoms and signs has pneumonia. However, accurate interpretation of a chest radiograph for pneumonia has multiple challenges: insensitivity in differentiating bacterial from nonbacterial cause, falsely negative in children examined early in the course of pneumonia or in dehydrated patients, lag in abnormal findings, substantial inconsistency in reading by radiologists, and influence of radiologist's knowledge of clinical information on accuracy of interpretation.[44,48,66–70] Prescription of an antibiotic has been linked to radiography,[67] but because routine chest radiography does not appear to alter the clinical outcome of acute LRI,[71,72] radiography should be restricted to special circumstances.

Chest radiography is indicated to confirm the presence and determine the location of pneumonia in children who are hospitalized or are severely ill; have recurrent disease or chronic medical conditions, poor response to initial antibiotic therapy, or complicated pneumonia; and in whom the diagnosis is uncertain or alternative causes of respiratory distress must be excluded.

Bilateral diffuse infiltrates are seen with pneumonia caused by viruses, *P. jirovecii*, *L. pneumophila*, and occasionally with *M. pneumoniae*. Both *C. pneumoniae* and *M. pneumoniae* (Fig. 34.1) cause focal radiographic abnormalities, which are out of proportion to clinical findings. Distinctly confined lobar or segmental abnormality or a large pleural effusion suggests bacterial infection

(Fig. 34.2), but rarely, *M. pneumoniae* or adenovirus can manifest with these findings.[73–75] "Round" pneumonia is the circular appearance of a lung infiltrate. It is common in children <8 years of age with bacterial pneumonia and most often is due to *S. pneumoniae,* although in rare cases, *H. influenzae, S. aureus,* or atypical organisms (*C. burnetii*) can be responsible.

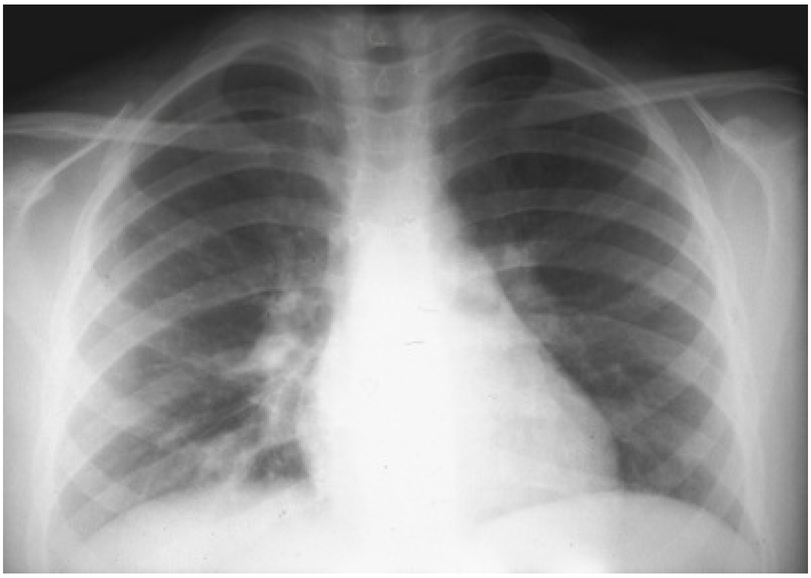

FIGURE 34.1 Plain radiograph showing patchy infiltrates in the right lower lobe, typical of *Mycoplasma* or other "atypical" pneumonias. (Courtesy of S. S. Long, St. Christopher's Hospital for Children, Philadelphia, PA.)

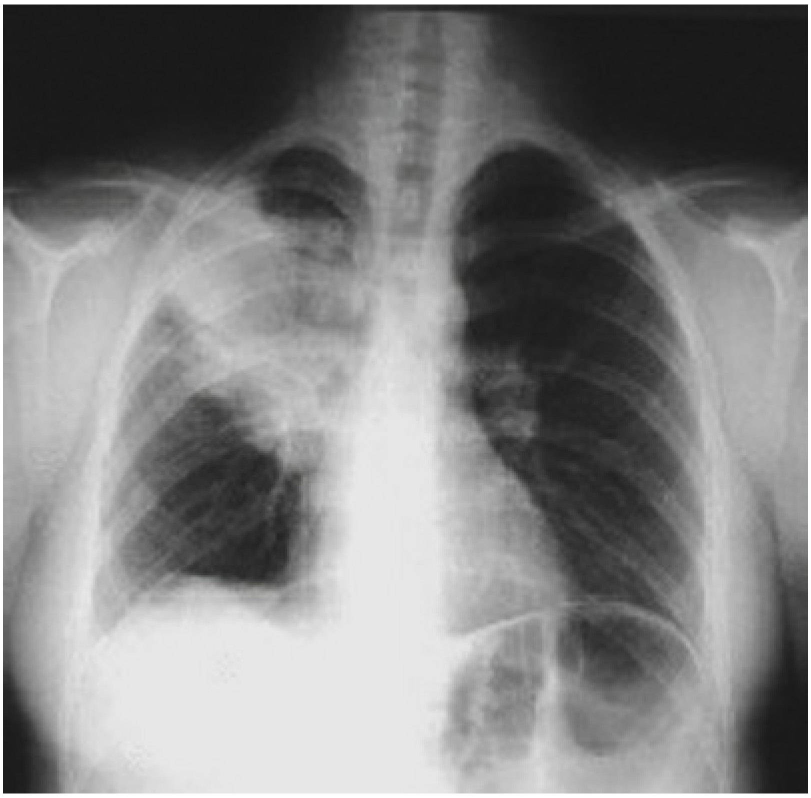

FIGURE 34.2 Plain radiograph showing consolidative pneumonia in the right upper lobe, typical of acute bacterial pneumonia.

Enlarged or calcified hilar lymph nodes suggest tuberculosis or a fungal infection such as *Histoplasma* or *Coccidioides*. *Mycoplasma* and chronic infection in cystic fibrosis can cause hilar lymphadenopathy. Pneumatoceles (thin-walled, air- or fluid-filled cavities) resulting from alveolar rupture usually are associated with infection due to *S. aureus* but can be a necrotizing component of *S. pneumoniae, S. pyogenes, H. influenzae,* gram-negative bacteria, or anaerobe infection. See Chapter 35 for other considerations.

Radiographic improvement of pneumonia lags clinical improvement, and complete resolution of radiologic abnormalities in children may take 4 to 6 weeks. Follow-up radiography is indicated only for persistent atelectasis, complicated pneumonia, recurrent pneumonia, or round pneumonia (to exclude tumor as the cause).[76,77]

A prospective study examining the utility of routine acute-phase reactants in children (WBC count and differential, C-reactive protein, erythrocyte sedimentation rate) with pneumonia concluded that these tests do not differentiate bacterial and viral pneumonia accurately.[78,79] A Cochrane meta-analysis found that patients with bacterial pneumonia usually have C-reactive protein level ≥4 mg/dL.[80]

Diagnosis of Specific Agents

Detecting the causative agent of pneumonia is very important for optimal management but is challenging without use of invasive techniques. Mild to moderately ill ambulatory patients usually can be managed empirically without specific diagnostic tests. Identifying the specific etiologic agent is important for all patients admitted to the hospital, those with underlying conditions, and when there is a community outbreak caused by an apparent emerging agent. A number of investigations may be necessary to confirm an etiologic diagnosis.

Viruses

A viral pathogen is best identified by recovering or detecting the organism in tissue culture or by detecting viral antigens or nucleic acid in respiratory tract secretions using immunofluorescence or polymerase chain reaction (PCR) techniques. Although viral culture is still considered the gold standard to confirm a diagnosis, clinical utility is low because of difficulty and duration of in vitro growth. Real-time PCR test panels rapidly detect common viral and atypical bacterial agents of CAP.[81] Added advantages include the facilitation of appropriate treatment decisions and cohorting of contagious patients. A nasopharyngeal wash or aspirate is the most sensitive specimen because it contains infected epithelial cells. Clinical interpretation of PCR detections is essential. Detection may be related to prolonged shedding.[23a] The presence of a viral agent in the upper respiratory tract does not exclude the presence of secondary bacterial pneumonia. Obtaining acute and convalescent sera to assess rising specific antibodies is usually confined to research settings.

Bacteria

The specific diagnosis of bacterial pneumonia is problematic in infants and children. You do not effectively cough up sputum. In older children, a sputum sample is considered appropriate for microbiologic evaluation when Gram stain reveals <10 squamous epithelial cells and >25 neutrophils per low-power field with a predominant organism. Cultures of nasopharyngeal specimens are not reliable. Tracheal aspiration is useful for culture if performed with direct laryngoscopy. Culture samples obtained through a catheter directly passed through a tracheostomy or an endotracheal or nasotracheal tube have limitations because of frequent contamination with upper respiratory tract organisms; these, however, could be evaluated as for a sputum sample. Quantitative culture performed on a bronchoalveolar lavage (BAL) specimen is useful when the isolate colony count is $>10^4$/mL. BAL is recommended in severely ill, intubated, or immunocompromised individuals not responding to initial antibiotic therapy.[82] The prevalence of bacteremia with pneumonia is reported to be 2.6% to 7%, depending on whether illness is mild or required hospitalization, but increases to 13% to 26% in cases of complicated pneumonia and parapneumonic effusion or empyema.[83–85] *S. pneumoniae* is the most frequent cause of bacteremic pneumonia with or without empyema.[85] Blood culture can confirm etiologic diagnosis, provide susceptibility test results, and alter antibiotic management.[82] Blood cultures are recommended in children who are hospitalized, especially with parapneumonic effusion or empyema.[41] Urine antigen test to detect pneumococcal infection in children in the US is no longer recommended because of low specificity for disease and low sensitivity. *Legionella* urine antigen testing has high sensitivity and specificity and should be performed selectively.[86] Research is ongoing to develop tests to identify pneumonia and characterize etiology (e.g., urine metabolic and exhaled breath condensate tests) that could aid clinical diagnosis in the future.[87–89]

Other Pathogens

M. pneumoniae is detectable by expanded respiratory panels for PCR testing used broadly. *Mycoplasma* culture also is available in some commercial and hospital laboratories but can take 3 weeks to complete. Cold agglutinins (*Mycoplasma*-specific IgM antibodies that agglutinate human red cells) are found in only 30% to 50% of individuals with *M. pneumoniae* pneumonia during the acute phase of the disease.[90] Low titers of cold agglutinins occur in other respiratory viral infections, some collagen vascular diseases, malignancies, and some tropical diseases, making this a less specific diagnostic test as well.[91] Complement fixation (CF) continues to be a widely used serodiagnosis test for *Mycoplasma* pneumonia with sensitivity and specificity of ≥90%.[92] A positive titer is defined as fourfold or higher increase in titer in paired sera or a single titer >1 : 32. The CF test can be negative in young children and in those with mild disease and can be falsely positive in certain inflammatory and autoimmune conditions (including neurologic diseases and bacterial meningitis) or acute pancreatitis because of cross-reactivity between host autoantibodies and the CF antigen.[93,94] Commercially available enzyme immunoassays for anti–*M. pneumoniae* IgM and IgA have unacceptably high false-positive rates.

Comparison of real-time PCR testing with microimmunofluorescence serology shows superiority of PCR for early detection of *C. pneumoniae* infection.[95] Interpretation of detection is required because asymptomatic infection occurs. Specific serology is effective in detecting infections with other agents that cause atypical pneumonia, namely *C. psittaci* and *C. burnetii.*

Screening tests for *M. tuberculosis* includes placing a skin test or obtaining a whole blood specimen for interferon γ release assay (IGRA). Patients and all immediate family members and other significant contacts also should be tested. In children with primary infection and acutely ill patients, IGRA and the skin test can be nonreactive because of general or specific anergy. Additionally, there are data on the utility of IGRA in diagnosis of tuberculosis in children <5 years of age. With suspicion of tuberculosis, multiple specimens should be obtained for smear and culture, including 3 daily samples of sputum (spontaneous or induced) or gastric aspirate, with or without BAL specimen.[96] PCR testing of specimens for *M. tuberculosis* compared with microscopy and culture has higher sensitivity in children with clinical disease.[97]

See also the pathogen-specific chapters in this text.

Treatment

All neonates with pneumonia are best managed, at least initially, in the hospital because of risk for rapid decompensation. Empiric antimicrobial therapy is similar to treatment for neonatal sepsis (see Chapter 92). Therapy is modified based on culture results, clinical response, and severity at presentation.

Outpatient Treatment

Infants 1 to 6 months of age with mild pneumonia can be managed as outpatients with close medical supervision, provided that they do not appear ill or have respiratory distress, hypoxemia (oxygen saturation <92%), feeding intolerance, signs of dehydration, or an underlying chronic medical condition.[98] It is preferable to hospitalize during the peak stage of illness in young infants <4 months of age suspected of having pertussis or viral bronchiolitis because of risk for apnea or hypoxia and, for pertussis, pulmonary hypertension. Infants 1 to 6 months of age should be hospitalized if they have uncertain follow-up, have failed initial oral antibiotic therapy, or have pneumonia that is necrotizing or associated with parapneumonic effusion, empyema, or lung abscess. Most children >6 months of age with mild to moderately severe pneumonia can be managed effectively without hospitalization provided they have reliable follow-up and absence of complication. Diagnostic tests to determine the etiology of pneumonia or radiography are seldom required or useful in most infants and children who are managed as outpatients. In influenza season, suspected influenza should be treated with oseltamivir. Antibiotic therapy is prescribed only when findings suggest bacterial infection. Treatment is empiric, based on likely etiologic agent by age, considering underlying medical conditions, and likely antimicrobial susceptibility, tolerability, and cost. Azithromycin is appropriate for the treatment of infants for infections with pertussis, *C. trachomatis* and *Ureaplasma.* Vigilence for drug-associated infantile hypertrophic pyloric stenosis is prudent, especially in infants <2 weeks of age.[99] Azithromycin dose for pertussis is 10 mg/kg per day once daily for 5 days.

High-dose amoxicillin therapy at 90 mg/kg/day is the preferred outpatient therapy for CAP in infants and children.[41,48,100,101] A pharmacokinetic simulation study predicted excessive failure of treatment of pneumonia due to *S. pneumoniae* with minimal inhibitory concentration (MIC) ≥2 µg/mL using high-dose amoxicillin in 2 divided doses.[102] Dosing in 3 divided doses is preferable in areas where *S. pneumoniae* with MICs ≥2 µg/mL occur.

In antibiotic-experienced children, high-dose amoxicillin-clavulanate (14 : 1 formulation) and ceftriaxone given intravenously are the most active agents for likely gram-positive or gram-negative respiratory pathogens, whereas trimethoprim-sulfamethoxazole, azithromycin, cefaclor, and cefprozil are the least active.[103] Cefuroxime axetil could be used in patients with pneumonia and non–type 1 hypersensitivity reaction to penicillin. Clindamycin could be used in patients with type 1 hypersensitivity reaction to penicillin and in those suspected to have staphylococcal pneumonia or aspiration pneumonia. In one study from the central US, however, 40% of *S. pneumoniae* cases were resistant to clindamycin.[103] Empiric use of cefdinir or azithromycin is an option for mild pneumonia in patients who are allergic or unresponsive to initial therapy with amoxicillin, but these drugs have limited activity against *S. pneumoniae* and nontypable *H. influenzae*.[103]

In children >5 years of age in whom *Mycoplasma* or *C. pneumoniae* are suspected, empiric treatment with a macrolide or doxycycline may be appropriate as single therapy or in combination with amoxicillin if pyogenic bacteria also are suspected. High-dose amoxicillin-clavulanate or clindamycin is effective for children with aspiration pneumonia. Fluoroquinolone therapy or treatment using agents with enhanced gram-positive activity (e.g., levofloxacin, moxifloxacin) can be considered in adolescents with frequent aspiration, as well as in those infected with atypical organisms, because their activity includes *M. pneumoniae* and *C. pneumoniae*.[104]

Duration of antibiotic therapy for pneumonia also is empiric and depends on several factors including patients' age, severity of illness, underlying illnesses, and response to therapy. In most cases the duration of therapy is 7 to 10 days. Oseltamivir therapy for influenza is initiated as soon as possible (i.e., before test results) for children at high risk for complications (e.g., underlying medical conditions including asthma) and for all children hospitalized with influenza. Oral oseltamivir phosphate is approved by the US Food and Drug Administration for children >2 weeks of age. Inhaled zanamavir also is approved as an alternative anti-influenza therapy in children >5 years of age with influenza and no underlying pulmonary disease.

Inpatient Treatment

Hypoxemia (oxygen saturation <92%) is the single most important indication for hospitalization because a hypoxemic child has greater risk for death than an adequately oxygenated child.[51] Other indications include cyanosis, rapid respiratory rate (>70 breaths/min in an infant or >50 breaths/min in a child), apnea, dyspnea, expiratory grunting, dehydration, toxic appearance, poor oral intake, recurrent pneumonia, underlying medical condition, or uncertain observation at home.

Supportive Therapy

Oxygenation is assessed continuously by measuring oxygen saturation or arterial P_{O_2}. Hypoxic infants and children may not appear cyanotic until terminal. Mental agitation, clinically evident as increased irritability, can be an indication of hypoxemia. Supplemental oxygen therapy is indicated in any patient whose oxygen saturation is persistently ≤92%. Sole reliance on pulse oximetry values, without blood gas determination, is hazardous in ill patients because hypercarbia is an important sign of impending respiratory failure.

Rapid breathing, fever, decreased oral intake, and fatigue increase the fluid requirements. Most patients can be hydrated orally if given small volumes of fluids frequently, but intravenous fluids usually are necessary for seriously ill children with rapid breathing because of increased likelihood for pulmonary aspiration. The syndrome of inappropriate secretion of antidiuretic hormone (SIADH) can occur in up to one third of patients hospitalized with pneumonia and is associated with more severe disease and with poor outcome.[105] Fluid restriction is required in these cases to improve outcome.

Malnutrition has been associated with a worse prognosis of pneumonia. Infants and small children fare better if fed in small quantities and more frequently to prevent aspiration.[106] Placement of an enteral feeding tube or parenteral nutrition may be necessary in a seriously ill or intubated child to maintain nutritional balance.

Persistent and high fever increases the basal metabolic rate and oxygen consumption. Similarly, pain interferes with the depth of breathing and with the ability to cough effectively. Age-appropriate antipyretic or analgesic agents may be necessary.

Oral antibiotics can be effective in certain hospitalized older infants and children with uncomplicated pneumonia who have good oral intake. Otherwise, initial intravenous therapy with ampicillin is appropriate. Ampicillin-sulbactam or a third-generation cephalosporin should be considered for those who previously received antibiotics or have severe pneumonia. A third-generation cephalosporin should be considered in areas where *S. pneumoniae* with MICs ≥2 μg/mL are prevalent. Intravenous clindamycin may be considered in patients with type-1 hypersensitivity to penicillin, suspected staphylococcal infection or aspiration pneumonia. Intravenous cefepeme, ceftazidime, or piperacillin-tazobactam is used for empiric therapy in immunocompromised patients with pneumonia, especially in those with neutropenia. Empiric antifungal therapy is considered initially or if there is inadequate response to antibiotic therapy. Vancomycin or linezolid usually is given for MRSA-confirmed infection or empirically in children with severe, life-threatening pneumonia. Patients with cystic fibrosis will need adequate antibiotic coverage for *S. aureus* and *Pseudomonas* spp. until sputum cultures guide further choices. Broad antibiotic therapy is reconsidered pending identification of an organism by susceptibility test results or pending the clinical course. Generally, appropriate oral antibiotic is selected to complete therapy for uncomplicated pneumonia when the patient responds to therapy and begins to tolerate oral fluids.

Viral pneumonia is complicated by bacterial superinfection with variable frequency.[107,108] Evidence suggests that withholding antibiotics from hospitalized children with pneumonia clinically compatible or proved to be of viral origin is safe and is preferable to broad use of empiric antibiotic treatment.[109] Use of specific antiviral therapy other than for influenza depends on the pathogen, the severity of the clinical course, and benefit-versus-risk considerations. Use of aerosolized ribavirin for the treatment of RSV and acute LRI is guided by recommendations from the American Academy of Pediatrics,[110] although the value of treatment has been questioned.[111]

Prognosis and Sequelae

Mortality due to CAP is uncommon beyond infancy in Europe and North America because of improved and enhanced immunization rates, early access to medical care, and availability of appropriate antimicrobial therapy. Most healthy children with acute LRIs recover without complications or sequelae. In some patients, especially premature infants, immunocompromised hosts, or children with chronic lung, neuromuscular, or sickle cell disease or cardiovascular disease, acute complications are more common.

Several epidemiologic studies have questioned a linkage of asthma and other respiratory morbidity occurring later in childhood to viral bronchiolitis or atypical pneumonia in infancy, but not to bacterial pneumonia.[112–114] RSV and *C. trachomatis*, in particular, have been implicated,[112–115] and one study linked asthma with *C. pneumoniae* infection.[116] Abnormal pulmonary function in adults has been reported after pneumonia or pertussis in early childhood.[117,118] Other longitudinal studies of pulmonary function in children with bronchiolitis, however, have suggested that abnormalities may have preceded the acute infectious illness.[119,120] Thus it remains unclear whether childhood pneumonia causes chronic pulmonary disease.

Prevention

Most respiratory viral infections are transmitted by direct inoculation from hands contaminated with respiratory secretions on to conjunctival and nasal mucosa. Spread by airborne droplets also occurs occasionally. Adequate hand hygiene by caregivers and medical personnel is the single most important method of preventing hospital-associated infections. Hospitalized patients with respiratory tract infection who are <5 years of age, and older children who are unable to follow proper respiratory etiquette, are cared for under isolation precautions (droplet and contact) to prevent transmissions by large droplets. Spread of infection by small droplets (pertussis) is reduced by use of airborne precautions in a negative-pressure room.

Universal immunization with pneumococcal conjugate vaccines, PCV7 and then PCV13, has reduced dramatically the incidence of invasive pneumococcal disease and pneumonia in children as well as in young adults and elderly people through community (herd) protection.[121–123] Children ≥2 years of age and adolescents at heightened risk for invasive pneumococcal disease should receive

PCV13 followed by pneumococcal polysaccharide vaccine 23 (PPV23).

RSV bronchiolitis and pneumonia can be reduced in high-risk infants by avoidance of multiple environmental risk factors (see Chapter 225). Monthly administration of RSV monoclonal antibody can reduce by 50% hospitalization due to RSV and is recommended for certain high-risk infections.[124] Annual vaccination against influenza is recommended for all individuals ≥6 months of age, with emphasis on strict implementation for those with underlying medical conditions such as chronic lung diseases (including mild asthma), neuromuscular disorders, congenital cardiac conditions, and diabetes who have high risk for severe and complicated lower respiratory tract influenza infection.[125,126] It is anticipated that prevention of influenza (and varicella) by immunization reduces the incidence of bacterial pneumonia in children due to *S. pneumoniae*, *S. aureus*, and *S. pyogenes*.

Acute Complicated Pneumonia

The acute complications of bacterial pneumonia include parapneumonic effusion, empyema, necrotizing pneumonia, pneumatocele formation, and lung abscess.

In the late 1990s, there was a significant increase in the relative incidence of complications from bacterial pneumonia in infants and children living in North America, the exact reason for which is still obscure.[16]

Pleural Effusion, Parapneumonic Effusion, and Empyema

Pleural effusion is the presence of abnormal fluid collection between the visceral and parietal pleurae. Pleural effusions are classified as a *transudate* or an *exudate* based on Light criteria for the biochemical characteristics of the fluid.[127] The relative concentration of pleural fluid protein to serum protein is <0.5 in a transudate versus >0.5 in an exudate (Table 34.3). Transudates are infrequently caused by infection, whereas exudates can have an infectious or noninfectious cause. Noninfectious causes of pleural effusions are listed in Table 34.4. Several drugs, including hydralazine, nitrofurantoin, dantrolene, amiodarone, methysergide, procarbazine, bromocriptine, methotrexate, and agents associated with a lupus-like reaction, are associated with pleural effusion.[128]

TABLE 34.3

Biochemical Characteristics of Parapneumonic Pleural Effusions

Laboratory Value	Uncomplicated Effusion Transudate	Complicated Effusion Exudate
pH	>7.2	<7.1
Glucose level	>40 mg/dL	<40 mg/dL
Lactate dehydrogenase concentration	<1000 IU/mL	>1000 IU/mL
Pleural protein–to–serum protein ratio	<0.5	>0.5

TABLE 34.4

Noninfectious Causes of Pleural Effusion in Children

Transudate	Exudate	
Hypoalbuminemia	Spontaneous chylothorax	Malignancy
Congestive heart failure	Posttrauma or postsurgical	Collagen vascular disease
Cirrhosis with ascites	Postoperative chylothorax	Pancreatitis
Myxedema	Pulmonary lymphangiectasia	Subphrenic or other intra-abdominal abscess
Peritoneal dialysis	Uremic pleuritis	Drug reaction
Central venous catheter leak	Sarcoidosis	Meig syndrome (pelvic tumor)
Fluid mismanagement	Dressler syndrome (postmyocardial infarction)	
Adult respiratory distress syndrome		

Parapneumonic effusion is an inflammatory fluid collection adjacent to a pneumonic process, seen overall in 2% to 12% of children with pneumonia and in up to 28% of hospitalized children.[129] Parapneumonic effusion can be classified as uncomplicated or complicated based on fluid pH, glucose, and lactate dehydrogenase (LDH) concentrations (see Table 34.3).[130] *Empyema* refers to purulent collection (exudate) in the pleural sac[131] and represents a spectrum from uncomplicated to complicated parapneumonic effusion.

Parapneumonic effusion usually occurs as a complication of pyogenic bacterial pneumonia but can occur occasionally, secondary to other etiologic agents (e.g., *Mycoplasma*, adenovirus)[132] or as a consequence of an infection from another contiguous site.[133] The estimated incidence of empyema in hospitalized children in the US was reported to be approximately 3.7 per 100,000 (range, 3.3–4.2) from 1997–2006, which was a 70% increase that occurred while the incidence of bacterial pneumonia, especially that due to *S. pneumoniae,* decreased.[134] The increase in empyema is thought to be related to increase in *S. pneumoniae* serotypes 1, 3, and 19A; *S. pyogenes*; and CA-MRSA.[135,136] Most cases of complicated pneumonia requiring surgical drainage occur in children <5 years of age.[137] Necrotizing pneumonia with pneumatoceles frequently coexists with empyema, predominantly in children <3 years of age.[138] The risk for developing empyema also is increased in children with certain underlying infectious (influenza) and medical conditions, including congenital heart disease, chronic pulmonary conditions, immune deficiencies, and neuromuscular disorders.[139,140] Complicated effusion or empyema is a serious illness often associated with significant morbidity (such as that needed for care in an intensive care unit), surgical drainage, longer hospital stay, and longer antibiotic course, resulting in high healthcare costs; mortality rates, however, have been low except in children <2 years of age.[85,141,142]

Etiologic Agents

S. pneumoniae is the most common cause of culture-confirmed and culture-negative parapneumonic effusions.[132] Although penicillin-nonsusceptible *S. pneumoniae* strains were recognized in the late 1980s to early 1990s, serotype 1, a highly invasive but penicillin-susceptible pneumococcal strain developed. During the late 1990s in Utah, *S. pneumoniae* serotype 1 emerged as a virulent agent of complicated pneumonia.[85] In the mid-2000s, before the introduction of PCV13, serotypes 1, 3, 7F, and 19A were detected in other areas of the US in more than half of cases of empyema in children.[132,143,144] In many cases, *S. pneumoniae* was detected by PCR in fluid or blood and not by culture, especially in patients pretreated with antibiotics. In a recent study from Greece, one third of 15 children with *S. pneumoniae* serotype 3 pneumonia and pleural effusion had been immunized with PCV13 after 12 months of age (with the then recommended 2 doses); no case occurred in children whose immunizations began in infancy and included all 4 recommended

PCV13 doses.[145] Universal childhood immunization against Hib has made Hib a rare cause of parapneumonic effusion. CA-MRSA is an important cause of complicated pneumonia[146,147]; in southeast Asia, *S. aureus* is the most common cause.[148] Less frequently, group A *Streptococcus*, *Pseudomonas aeruginosa,* mixed anaerobic pathogens, *Mycobacterium* spp. and, rarely, fungi and parasites can be the etiologic agents.[149] Although effusion can accompany pneumonia due to *M. pneumoniae* and common viruses, they seldom are large enough to require intervention.[149,150] Parapneumonic fluid, other than in *S. aureus* infection, frequently is sterile, especially if the patient has received antibiotics or when the infection is caused by fastidious organisms.[132,143,146] In such situations, PCR testing often can confirm the etiology.

Pathogenesis and Pathologic Findings

Under normal circumstances, the pleural space contains a small amount (0.1–0.2 mL/ kg) of low protein fluid that forms a lubricant film between the two layers of the pleura.[151] The pleural circulation is maintained by a delicate balance between secretion and absorption of pleural fluid by lymphatic vessels. When this balance is disturbed, fluid accumulates. Transudate occurs when there are changes in the hydrostatic forces with normal capillary permeability, whereas exudate results when there is increased capillary permeability and lymphatic obstruction.[152,153] Pleural mesothelial macrophages contribute to the innate local defense against infection.[154] Pathogens can gain entry into the pleural space by direct extension from the alveoli, by hematogenous spread from the skin surface through a penetrating injury, from rupture of the esophagus, or from an intra-abdominal site through the diaphragm.[155] Direct extension from the alveoli is by far the most common. Certain pathogens such as *S. aureus, S. pneumoniae,* and *S. pyogenes* demonstrate tropism for the pleural surface for reasons that are not well understood but that likely include virulent factors such as exotoxins, endotoxins, or attachment molecules. Exposure of the pleural mesothelial cells to lipopolysaccharide, thrombin, or bacteria can incite an innate and adaptive inflammatory response causing pleural mesothelial macrophage dysfunction.[156,157] Vascular endothelial growth factor is released, which potentiates endothelial injury, increased capillary permeability, and extravasation of pulmonary interstitial fluid into the pleural space.[158] Mesothelial cells recruit neutrophils and monocytes and secrete large amounts of chemokines, including interleukin-8 (IL-8), into the pleural fluid that, when inhibited by bacterial proteins, results in an acidic, purulent fluid (i.e., empyema).[159] Acidic environment of the pleural fluid both suppresses bacterial growth and interferes with antibiotic activity. With disease progression, more inflammatory cytokines are released, and there is activation of coagulation leading to deposition of fibrin.

Three stages in the natural course of empyema are recognized. First, in the *exudative phase*, the fluid has low cellular content, normal glucose, and normal pH. Second, in the *fibrinopurulent phase*, frank pus containing neutrophils and fibrin is formed, and glucose and pH of fluid are low. This fibrinous pus coats the inner surfaces of the pleura, interfering with lung expansion, and leads to loculations. Third, in the *organizational phase* (late stage), fibroblasts migrate into the exudate from visceral and parietal pleurae, producing a nonelastic membrane called the *pleural peel*. Before the availability of antibiotics, spontaneous drainage through the chest wall (empyema necessitans) or into the bronchus (bronchopleural fistula) sometimes followed. Such events now are rare and usually are due to healthcare-associated antibiotic-resistant bacteria or insidiously progressive actinomycosis.

Clinical and Radiographic Manifestations[85,138,141,149]

Effusion should be suspected when the response of a lobar, lobular, or alveolar pneumonia to appropriate antibiotic therapy is slow, or if there is clinical deterioration during treatment. Symptoms of pleural effusion can begin nonspecifically with malaise, lethargy, and fever, followed by cough and rapid breathing, the latter which are expected in >90% of children with complex parapneumonic effusion.[141] Dyspnea, difficulty breathing, and grunting become apparent as the effusion progresses. Pain in the chest or abdomen develops on the involved side and is associated with high fever, chills, and rigors. The child may splint or lie on the involved side to minimize pain. The patient usually is ill, toxic appearing, and febrile, with significant tachypnea and shallow respirations, or can have severe respiratory distress, hypotension, and septic shock. Scoliosis may be noted on the involved side, and the affected side may be tender to palpation. On auscultation of the involved side, breath sounds usually are frankly diminished, crackles from the associated pneumonia may be audible, pleural rub may be audible when the effusion is small, and the percussion note is dull when the effusion is free flowing. By contrast, dullness can decrease as the effusion organizes.

Plain chest radiography is more sensitive than physical examination but less sensitive than ultrasonagraphy in detecting small effusions.[160] A chest radiograph can indicate size and loculation of effusion and whether drainage likely is indicated and can define parenchymal lung consolidation as well as an unexpected underlying cause of the effusion, such as a mass, hilar adenopathy, or cardiomegaly. Blunting of the costophrenic angle, thickening of the normally paper-thin, pleural-shadow, and a subpulmonic density all suggest pleural effusion (Fig. 34.3). Compression of the lung, with shift of the trachea away from the effusion, may be seen when the effusion is large, usually ≥1000 mL.[161] Lateral decubitus films can differentiate free effusion from loculated collections, pulmonary consolidation, and pleural thickening. Chest radiographs, however, cannot differentiate between a parapneumonic effusion and an empyema.[149] Ultrasonography is the imaging modality of choice because it is portable, inexpensive, and involves no radiation exposure; differentiates parenchymal from pleural space disease; helps localize and estimate the size of an effusion precisely; identifies the best site for thoracentesis and chest tube placement; and is superior to computed tomography (CT) in detecting early loculation and septation.[162] Quality of ultrasonography is dependent on level of experience of the operator. Although CT is not necessary routinely to differentiate simple parapneumonic effusion from empyema, CT may be indicated to evaluate parenchymal disease (necrotizing pneumonia or lung abscess), to determine noninfectious causes, or to aid the surgeon before thoracotomy or thoracoscopy.[16]

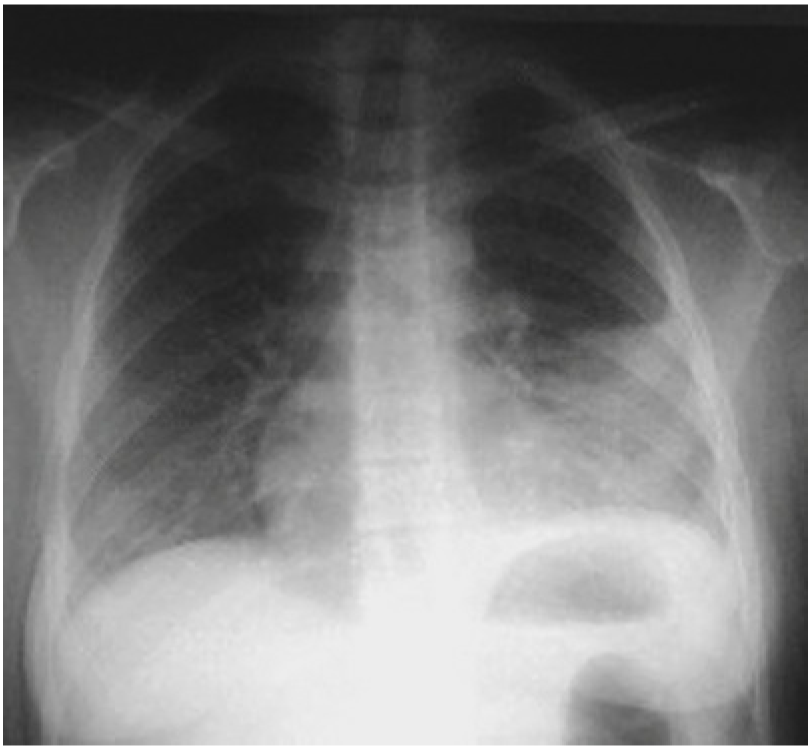

FIGURE 34.3 Plain radiograph showing left lower lobe pneumonia and a parapneumonic effusion, typical of acute bacterial pneumonia.

Laboratory Findings and Diagnosis

Children with parapneumonic effusion or empyema often have an elevated peripheral WBC count, left shift of neutrophils, elevated C-reactive protein, and thrombocytosis (>500,000 platelets/mm^3). Hypoalbuminemia can occur if the effusion is large and proteinaceous and hyponatremia raises consideration of SIADH. Blood cultures are obtained before therapy because a positive result (10%–22%) is useful for management when pleural fluid is sterile.[85,145] Culture of sputum or tracheal aspirate, if possible, may be useful. Gram staining determines whether the quality of the sample is good (>25 neutrophils/low-power field and absent squamous epithelial cells) and if a single organism type is predominant.

Pleural fluid specimen is inspected to determine color, odor (putrid odor being pathognomonic of anaerobic infection), and character (bloody, purulent, seropurulent, or serosanguineous); centrifuged if cloudy (persistent cloudiness is suggestive of a chylothorax); and analyzed for total WBC count with differential and by special stains and culture. Cellular histology and flow cytometry are performed if infectious etiology is uncertain. Empyema is likely when biochemical analysis reveals pleural fluid-to-serum ratio for LDH >0.6, pH <7, glucose <40 mg/dL, and LDH >1000 U/L.[163] Because biochemical analysis rarely influences management, Pediatric Infectious Diseases Society and Infectious Diseases Society of America guidelines do not recommend evaluation unless the patient has an underlying condition (e.g., collagen vascular disease).[41] Cytokine levels in pleural fluid, especially IL-8, are expected to be high in empyema.[156] IL-8 level may be useful to differentiate a complex from simple parapneumonic effusion.

Total and differential WBC count of pleural fluid is helpful in differentiating bacteria, mycobacteria, or fungi infection and malignancy.[149] Presence of >50,000 neutrophils/mm^3 is usual in empyema. Lymphocytic predominance suggests tuberculosis and some fungal or *Mycoplasma* infections but also can indicate a chylothorax. Mixed mononuclear cell types suggest a more chronic process, such as tuberculosis, malignancy, uremia, or collagen vascular disease. Eosinophilic effusion in adults, especially with air or blood in the pleural space, suggests tuberculosis, asbestosis, malignancy, paragonimiasis, drug-related hypersensitivity, pleurisy, collagen vascular disease, other parasitic infections, or an idiopathic case (14%–20%).[164–167]

Bacteriologic examination always includes Gram stain and culture for aerobic and anaerobic bacteria. Acid-fast stain and culture for *M. tuberculosis*, as well as fungal stain and culture, should be obtained from both fluid and sputum when clinically indicated. Rapid non–culture-based diagnostic tests such as PCR, immunoassay, and rapid antigen testing increasingly are performed because their rate of culture positivity is low and the knowledge of etiology aids management.[168]

Tuberculous pleural effusion usually is caused by a delayed hypersensitivity reaction to mycobacterial antigens in the pleural space.[169] Diagnosis often is delayed because of paucity of organisms in pleural fluid, anergy to tuberculin skin test, and IGRA in blood.[170,171] High levels of adenosine deaminase (>40 IU/L) and interferon γ (>75 pg/mL) in pleural fluid are very suggestive of tuberculous effusion.[172] Rapid and accurate diagnosis, as well as prediction of rifampin resistance, is possible using the Xpert

MTB/RIF (Cepheid, Sunnyvale, CA) assay on pleural biopsy and pleural fluid specimens in patients with suspected tuberculous pleural effusion who have a negative sputum smear for acid-fast bacilli.[173] Pleural biopsy is considered to diagnose other granulomatous infections (histoplasmosis, other fungal infections, and *Francisella tularensis)* and malignancies.

Management

The main objectives of therapy are eradication of infection and reestablishment of pleural fluid circulation, thereby reinstating normal lung function.[174] These can be achieved by either medical or surgical interventions depending on the age of the patient, size of the effusion, severity of respiratory distress, loculation, and failure of initial medical therapy. Supportive care using appropriate antipyretics, analgesics, oxygen supplementation, and fluid therapy must be instituted early and patients must be monitored closely to recognize respiratory deterioration, central respiratory depression from excessive analgesics, or fluid overload related to SIADH. Chest physiotherapy is avoided because this causes discomfort and can further compromise the respiratory effort.[149]

Antimicrobial Therapy.

In choosing therapy, consideration is given to probable pathogens (predicted by age), pathogen and geographic resistance patterns, clinical circumstances (community or healthcare onset), host factors (immunocompetent or compromised), radiographic findings, and Gram stain and culture of the pleural fluid. Children with small, uncomplicated effusion can be managed as outpatients with an empiric antibiotic regimen as for CAP. In most hospitalized patients, ceftriaxone or cefotaxime given intravenously is recommended as empiric therapy to adequately treat *S. pneumoniae* and *S. pyogenes*. Vancomycin is added if the patient is very ill appearing or CA-MRSA or hospital-acquired MRSA is considered a potential pathogen. In areas where CA-MRSA is highly clindamycin susceptible, clindamycin could be an adequate addition. Vancomycin has poor pharmacokinetics for infections in the lung. Other agents with good MRSA activity include linezolid, telavancin, ceftaroline, and quinupristin-dalfopristin; these agents are considered second-line treatment for patients who do not respond to vancomycin therapy. Daptomycin should not be used because it is inactivated by surfactant. In patients with suspected pneumonia aspiration, clindamycin can be used instead of vancomycin to cover anaerobic bacteria. In cases in which atypical pathogens are suspected, a macrolide (for children <7 years) or doxycycline (for children >7 years) may be added. When a specific pathogen is detected, or when the clinical course and microbiologic screening cultures make Staphylococcal infection highly unlikely, the antibiotic spectrum should be narrowed. Duration of parenteral therapy and total treatment is individualized on the basis of clinical response and adequacy of drainage. It is common practice to replace parenteral therapy with oral therapy when substantial improvement occurs and the patient has good oral intake, with continuation of antibiotics for a total course of 2 to 4 weeks for empyema.[41] The treatment may be prolonged when drainage is delayed and systemic manifestations are protracted. In circumstances in which the effusion persists and the microbial etiology is unknown, it is important to remember that even with optimal antibiotic therapy, fever, anorexia, and toxicity can be due to a prolonged inflammatory response. Additions or changes in appropriately selected antibiotic therapy should be avoided.

Surgical Intervention.

Thoracentesis is recommended to relieve moderate to large effusions, defined as fluid layering >1 cm on lateral decubitus radiograph or opacifying more than one fourth of the hemithroax.[41,149,162] A therapeutic approach to moderate-sized, nonloculated parapneumonic effusion not associated with respiratory compromise is to slowly drain 10 to 20 mL/kg, send the fluid for microbiologic studies, and begin empiric antibiotic therapy intravenously. It is important not to drain fluid too rapidly because reexpansion pulmonary edema can occur, causing increased morbidity and even mortality.[175] The course is observed over 48 to 72 hours. Many patients improve. If the patient does not improve or worsens, ultrasonography is performed to determine the extent of reaccumulation. If fluid has reaccumulated, continuous drainage is required; if not, an antibiotic regimen is reconsidered. For patients with a large effusion or patients with respiratory compromise, a chest tube is placed as soon as possible for continuous drainage. A small bore chest tube is preferable for patient comfort and was associated with shorter hospital stay and found to be superior to surgical stiff drains in two studies.[176,177] Chest radiography is repeated to verify chest tube placement and to exclude the development of pneumothorax during placement. Complications of chest tube placement include bleeding or infection at the exit site, persistent atelectasis, development of bronchopleural fistula, or (very rarely) laceration of the lung.[178]

Loculated complex parapneumonic effusion or empyema usually requires more aggressive management, but optimal management remains controversial. According to the British Thoracic Society and American Pediatric Surgical Association guidelines,[149,162] medical therapy (chemical debridement with fibrinolysis) should be considered as initial therapy of choice followed by video-assisted thoracic surgery (VATS) in patients who fail medical therapy. Recommendations are based on several studies showing comparable outcomes and complications for procedures, with safety and cost favoring chemical debridement with fibrinolysis.[179,180] However, a 2005 meta-analysis showed that primary operative therapy compared with nonoperative therapy was associated with a lower cumulative in-hospital mortality rate (0% vs. 3.3%) and rate of reintervention (2.5% vs. 23.5%). In addition, primary operative therapy was associated with shorter duration of hospitalization (10.8 vs. 20 days), chest tube days (4.4 vs. 10.6 days), and antibiotic therapy (12.8 vs. 21.3 days), respectively.[181] Most experts agree that either approach is reasonable and that choice of procedure will depend on local expertise, cost considerations, and patient preference.

Available fibrinolytic agents include urokinase, streptokinase, and alteplase. Alteplase is the most commonly used fibrinolytic agent in the US because urokinase is not available and streptokinase has limited efficacy and possible allergic reactions.[182] Common adverse effects of fibrinolytic therapy include fever, discomfort, intrapleural bleeding, and anaphylaxis.[177] Fibrinolysis is contraindicated in patients with bronchopleural fistula or when there is an air leak because this could cause tension pneumothorax.

In VATS surgery, fibrinous material is debrided, loculations are broken, and drainage of purulent material from the pleural space is established. VATS is most effective when performed early in the course of complex effusions or empyema, has good outcomes, and is relatively safe. Compared with open thoracotomy, VATs is less invasive and has a comparable success rate, earlier resolution of the disease, shorter hospital stay, and better cosmetic appeal.[183,184] Partial decortication frequently can be accomplished when necessary. The few contraindications to performing VATS include inability to access the pleural cavity because of thick, purulent fluid and severe fibrosis.

Bronchoscopy may be indicated in anaerobic infections to hasten drainage or the removal of a foreign body. Open pleural decortication is reserved for patients who have come to optimal management late and have entrapment of lung with persistent and severe restrictive lung disease.

Most children improve after surgical drainage, as evidenced by improved activity, appetite, vital signs, and chest physical findings and resolving acute phase reactants. After radiographic examinations related to chest tube removal, follow-up chest radiograph usually is not necessary unless the child has persistent symptoms or has had a previous episode. Follow-up chest radiograph for the latter indication should be delayed 4 to 6 weeks because radiographic resolution lags clinical resolution.[174]

Prognosis

Most children with complex parapneumonic effusion or empyema recover completely despite the severity of their initial presentation. The mortality rate was about 3% in previously healthy children medically managed with antibiotics and chest tube drainage, but no deaths were reported in children who underwent a fibrinolytic procedure, VATS, or open thoracotomy.[181] Historically, mortality was highest in small infants.[185] Increased morbidity can be expected in children with underlying medical conditions (e.g., malnutrition, neuromuscular disorders, or chronic pulmonary disease) or with infection due to MRSA or multidrug-resistant organisms. A long-term prospective follow-up study of children treated for complex effusions or empyema showed no sequelae despite substantial complications within 1 month of illness.[186] A recent study evaluating the long-term effect of parapneumonic effusion, especially in children with prior history of asthma, concluded that there were no long-term important effects despite small changes in lung function and exercise capacity.[187]

Necrotizing Pneumonia and Lung Abscess

Necrotizing pneumonia and lung abscess represent the spectrum of disease. The etiology and course in children differ compared with adults. Lung abscess usually occurs as a consequence of a localized lung infection by particularly virulent, pyogenic bacteria. Necrotizing pneumonia in an otherwise healthy child usually resolves with antimicrobial treatment, but occasionally can progress to formation of pneumatoceles (blebs in the lung parenchyma created by coalescence of alveolar spaces after rupture of septa), lung abscess, or bronchopleural fistula. Lung abscess is usually the outcome of widely variable pathogenic processes; it can be the consequence of (1) necrotizing pneumonia; (2) localized infection after aspiration of heavily infected mouth secretions (sometimes along with a foreign body); (3) focal infection of the lung that occurs during high-grade bacteremia or as a result of infarcting septic emboli from distant sites; or (4) complication of a subacute or chronic airway infection seen as a late result of cystic fibrosis, after prolonged intubation, or after nosocomial pneumonia. In immunocompromised hosts, bacteria or fungi can invade the vessel walls, leading to subsequent lung infarction and necrotizing pneumonia (see Chapter 36).

Etiologic Agents

Community-acquired bacterial pneumonia can result in necrosis of parenchyma, which often is discovered on chest radiography or increasingly because CT is performed in a child with prolonged fever and ill appearance.[188] The causative pathogen is not identified in many cases, but when detected, *S. pneumonia* is most common.[189] Less commonly, *S. aureus* (especially CA-MRSA), *S. pyogenes* (especially after influenza illness), β-hemolytic streptococci (Lancefield groups C and G), and other streptococcal species are causative.[190–192] Pneumatoceles can complicate *S. pneumoniae* or *S. aureus* pneumonia, and the latter can lead to abscess formation.[190,193,194] Rarely, severe *M. pneumoniae* pneumonia is accompanied by abscess formation.[195,196]

When pneumonia follows aspiration of oropharyngeal flora, or regurgitated stomach contents and obstruction, the volatile fatty acids produced by anaerobic bacteria are particularly prone to cause necrosis and abscess. Most aspiration pneumonias, lung abscesses, and empyema are mixed infections.[197,198] The predominant anaerobic bacteria isolated are *Peptostreptococcus*, *Fusobacterium*, *Prevotella melaninogenica,* and *Porphyromonas* spp.[197] *Veillonella* may be more likely isolated in children with prior surgery, malignancy, corticosteroid therapy, aspirated foreign body, or immunodeficiency.

Single or multiple lung abscesses (usually due to *S. aureus* infections) can result from right-sided endocarditis, severe septicemia, or distant osteoarticular or deep muscle infection with thrombosis. Necrotizing pneumonia and lung abscess also can follow endovascular infection or phlebothrombosis of the large veins in the neck (Lemierre syndrome).[199] *Fusobacterium necrophorum* is the most common pathogen, but *S. aureus,* α-hemolytic streptococci, *Streptococcus anginosus* group, *Actinomyces* spp., or molds can be causative.[200]

Lung abscesses in intubated infants and children usually are due to hospital-associated pathogens.[201] Abscesses can develop in the later stages of cystic fibrosis secondary to chronic bronchiectasis. In such cases, *S. aureus, P. aeruginosa,* and atypical mycobacteria should be considered.[202,203]

Pathogenesis

Necrotizing pneumonia is a consequence of severe inflammation confined to a cluster of alveoli or a lobe resulting in significant parenchymal damage and tissue necrosis. Abscess formation can follow even when treatment is adequate but more frequently when treatment is delayed or inadequate.

Aspiration and obstruction of the airways predispose to polymicrobial and anaerobic lung abscess. Risk factors include decreased level of consciousness due to neurologic disease, anesthesia, alcohol, or drugs or during surgical instrumentation; neuromuscular disorders depressing the gag reflex; esophageal abnormalities; gastroesophageal reflux; and prolonged endotracheal intubation. Poor dental hygiene and periodontal infection increase the density of anaerobes and predispose to lung abscess in adolescents. Impaired phagocytic responses as seen in neutropenic patients or after viral infections with influenza, measles, and VZV also can predispose to complicated pneumonia. Aspirated acid contents of the stomach cause chemical injury to lung tissue.[204] Location of abscess favors the middle or right lower lobe in patients who aspirate while erect, and favors the posterior upper or lower lobes in the supine patient. Abnormal drainage as occurs in congenital pulmonary sequestration, lobar emphysema, and pneumatocele formation can predispose to abscess formation. Experimental studies in animals show a timeline from aspiration to pneumonia to lung abscess of at least 1 to 2 weeks.[205]

Heavy seeding of the pulmonary circulation during high-grade bacteremia can lead to lung abscess, as can pulmonary infarction associated with septic embolization. These circumstances usually lead to multiple abscesses, unilaterally or bilaterally. Chronic airway disease, cystic fibrosis, congenital ciliary dysfunction, and bronchiectasis predispose to lung abscess. The inherited abnormalities of humoral or cellular immune responses, such as chronic granulomatous disease or hyper-IgM syndrome, permit persistence of certain pathogens, which can result in abscess formation.

Clinical Manifestations

Clinical manifestations of necrotizing pneumonia are similar to but usually more severe than those of nonnecrotizing pneumonia due to the same bacteria. The evolution from necrotizing pneumonia to abscess frequently is insidious.[206] Lung abscess after aspiration usually manifests 1 to 2 weeks after the event. Prolonged fever and a toxic appearance or persistent hypoxia despite appropriate antimicrobial therapy is characteristic. Fever is the most common sign in patients with lung abscess.[188] Cough, dyspnea, and sputum production are present in approximately one half of patients.[188,206] Cough usually is nonproductive, but with spontaneous rupture of the abscess into the bronchus, it can be massively productive. Hemoptysis can be seen in necrotizing pneumonia. Older children may report chest pain with or without radiation. Other symptoms are nonspecific and include rhinorrhea, sore throat, lymphadenopathy, decreased appetite, irritability, and malaise or lethargy.[188] Physical findings also are nonspecific unless there is accompanying pleural fluid.

The differential diagnosis of lung abscess includes common necrotizing bacterial infections as well as tuberculosis, nocardiosis, fungal infections, melioidosis, paragonimiasis, and amebic abscess. Certain noninfectious diseases, such as malignancy, sarcoidosis, and pulmonary infarction, can produce lesions that mimic abscess on chest radiograph.

Diagnosis

A chest radiograph should be obtained in a child whose symptoms do not respond to appropriate antibiotic treatment (Fig. 34.4). The initial finding usually is an irregular cavitary lesion (with or without a thick wall) with air-fluid level adjacent to a segmental or lobar lung infiltrate, without prominent hilar adenopathy. Multilobar involvement can be seen in patients with underlying immune dysfunction or after septic embolization.[207] Chest radiography may not be diagnostic initially in approximately 20% of cases. In one study of 18 cases, abscess location was the right lower lobe (8), left lower lobe (6), right upper lobe (3), and left upper lobe (1).[206] CT is more sensitive than plain radiography and often is useful to define the extent of disease, underlying anomalies, presence or absence of a foreign body (Fig. 34.5), and endobronchial obstruction and to distinguish parenchymal abscess from air-fluid levels in the pleural space.[208]

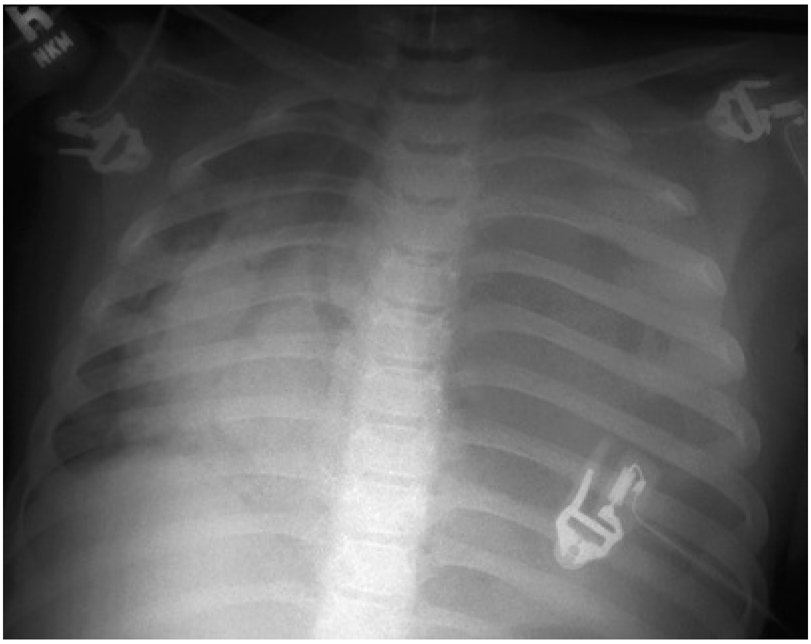

FIGURE 34.4 Anaerobic pleural empyema in a 5-year-old girl who came to medical attention because of a 1-month history of abdominal pain, tiredness, and constipation, but no history of an aspiration event, fever, respiratory distress, or cough. This radiograph was obtained after an acute respiratory event during evaluation for constipation. Note complete opacification of the left hemithorax with severe shift of the heart and trachea to the right. Three liters of putrid pus was drained, revealing a left lower lobe abscess. Gram stain and culture revealed polymicrobial anaerobic and facultative oropharyngeal flora. (Courtesy of E. N. Faerber and S. S. Long, St. Christopher's Hospital for Children, Philadelphia, PA.)

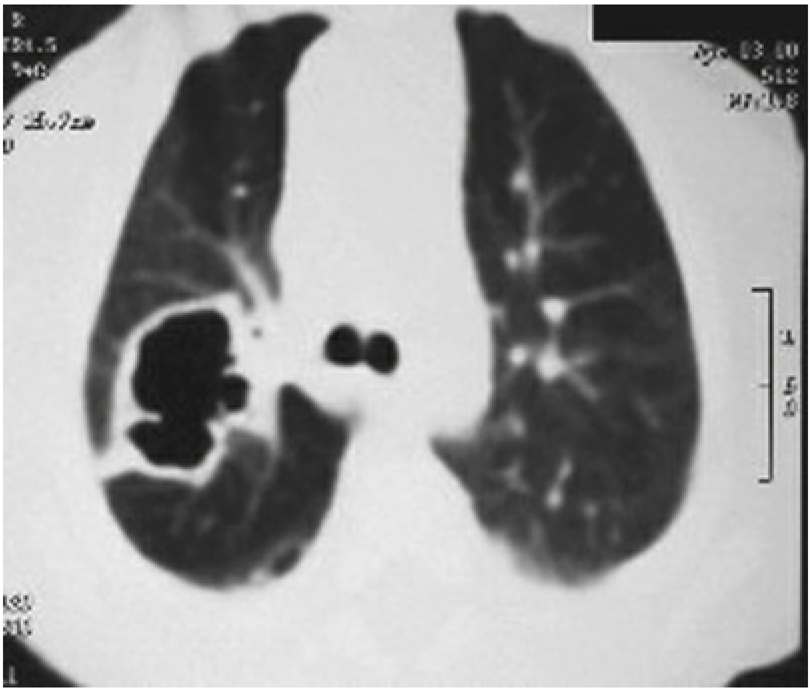

FIGURE 34.5 Lung windows of computed tomography study showing right lower lobe abscess.

Ultrasonography using color Doppler is a powerful diagnostic tool to differentiate fluid-filled lung abscess from empyema and has the advantages of greater convenience, lower cost, and avoidance of radiation.[209]

Bronchoscopy may be a therapeutic means to facilitate the removal of a foreign body or to promote the drainage of purulent fluid, or both.[206] Only 3% of bronchoscopic specimen cultures grew an organism that later was recovered from a lung abscess.[210] Cultures of sputum, BAL, or blood are of limited diagnostic value compared with culture of direct lung aspirate. In one study, 94% of the specimens obtained by transthoracic aspiration yielded a pathogen despite prior receipt of an antibiotic compared with only 11% of sputum cultures and 3% each of blood and BAL cultures.[210] Ultrasound-guided transthoracic aspiration technique was used successfully to obtain specimens for diagnosis to drain lung abscesses in 3 premature infants.[211] There is a potential risk for spillage of contaminated fluid into the pleural space during ultrasound- or CT-guided transthoracic aspiration; procedures are reserved for patients not improving clinically on antibiotic therapy and for those who have a large abscess that must be drained.

Management

Prolonged antibiotic administration is the mainstay of therapy for necrotizing pneumonia and lung abscess. Duration of therapy is based on clinical response and usually is 4 weeks, or at least 2 weeks after the patient becomes afebrile and has clinical improvement. In most cases, parenteral therapy is initiated. Two randomized clinical trials in adults found clindamycin to be superior to penicillin for the treatment of anaerobic lung abscess.[123,212,213] A randomized clinical trial for treatment of children with aspiration pneumonia found no difference between these two drugs. Ampicillin-sulbactam has an excellent spectrum of activity against organisms in aspiration lung abscesses.[214] Parenteral clindamycin is appropriate empiric therapy in children with complicated lung infection possibly due to *S. aureus* or CA-MRSA. Vancomycin is an alternative in patients with allergy or where clindamycin resistance of *S. aureus* is prevalent. Other antistaphylococcal medications, such as linezolid, could be used in case of allergy or poor response to vancomycin or clindamycin.[215] Combination therapy with ticarcillin or piperacillin and a β-lactamase inhibitor (e.g., tazobactam) with or without an aminoglycoside may be considered when necrotizing pneumonia follows aspiration in a hospitalized child or in a child for whom an Enterobacteriaceae (e.g., *E. coli, Klebsiella* spp.) or *P. aeruginosa* infection is suspected or has been identified from a percutaneous lung aspirate. Metronidazole would be effective treatment for β-lactamase–producing anaerobes in lung abscess after aspiration but cannot be used alone without an agent active against aerobic and microaerophilic streptococci.[216]

Necrotizing pneumonia or abscess frequently is complicated by parapneumonic effusion, which benefits from percutaneous drainage or other invasive procedures depending on size and other clinical factors. Previously, percutaneous drainage of the abscess often was complicated with the development of bronchopleural fistula.[217,218] Because of expected good outcome with medical therapy, percutaneous drainage should be considered only in patients with poor response 5 to 7 days after initiating therapy, for an abscess >4 cm in diameter, for presence of mediastinal shift, or for an abscess resulting in ventilator dependency. Surgical wedge resection or lobectomy is rarely required and is reserved for cases in which medical management and drainage fail, or bronchiectasis has occurred.

Prognosis and Complications

Most cases of necrotizing pneumonia in otherwise healthy children resolve with antibiotic treatment alone.[188] Similarly, 80% to 90% of lung abscesses resolve with antibiotic therapy alone provided there is no associated bronchial obstruction or underlying lung disease such as cystic fibrosis. Fever can persist for an average of 4 to 8 days despite appropriate therapy. Complications due to lung abscess are rare in developed countries and in otherwise healthy hosts. These could include intracavitary hemorrhage with hemoptysis, spillage of abscess with spread of infection to other parts of the lung, empyema, bronchopleural fistula, septicemia, cerebral abscess, and SIADH.

Persistent and Recurrent Pneumonia

Robert R. Wittler

Persistent pneumonia has been defined as continuation of symptoms and radiographic findings beyond 4 weeks given that most acute pneumonia improves clinically and radiographically within that time.[1] Persistent or residual abnormalities occur in 10% to 30% of children with radiographically confirmed community-acquired pneumonia (CAP) 3 to 7 weeks after initial imaging.[2,3] In adults with CAP, clinical resolution occurs in more than 85% of cases and radiographic resolution in 67% of cases by 4 weeks after onset.[4] In both adults and children with CAP, radiologic abnormalities lag behind clinical resolution.[4] Although pneumonia due to respiratory syncytial virus (RSV) or parainfluenza virus clears within 2 to 3 weeks,[5] pneumonia due to adenovirus can cause persistent abnormalities for up to 12 months.[6] Thus, in children making an uneventful clinical recovery from a first episode of uncomplicated CAP, a repeat chest radiograph is not recommended routinely.[7]

Recurrent pneumonia has been defined as occurrence of two or more episodes of pneumonia in a 1-year period or three or more episodes in any period, with radiographic resolution between episodes.[1] Using this definition, approximately 8% of children requiring hospitalization for pneumonia would be identified as having recurrent pneumonia.[8] In children with underlying conditions such as cystic fibrosis (CF) or pulmonary sequestration, complete resolution does not occur between exacerbations.

Radiographic documentation of episodes is essential for categorization because precise clinical distinctions are made infrequently and “pneumonia” is the diagnosis sometimes conveyed to the parent (or the parent perceives) for conditions such as bronchiolitis, bronchitis, asthma, or persistent cough.

Although a chest radiograph is not necessarily indicated to confirm the diagnosis of acute pneumonia in previously healthy outpatients, nor indicated routinely at the end of treatment of the first episode of acute pneumonia requiring hospitalization,[7] a history of prior episodes, especially in the same lobe, and persistence or recurrence of symptoms are indications for initial and follow-up radiographic evaluations.[9,10] In a child with a history of “recurrent pneumonia,” documenting a normal radiographic appearance 2 months after an acute episode (the time at which radiographic findings are expected to be normal in more than 90% of cases) is the most useful step in shaping a differential diagnosis. Before investigations are initiated for persistent or recurrent pulmonary infection, radiographs should be obtained and reviewed with a radiologist experienced in disorders of children to define the abnormalities precisely and to consider both infectious and noninfectious processes as well as underlying conditions and anatomic abnormalities.[1]

The differential diagnosis for and clinical approach to recurrent pneumonia in children are distinct from those for persistent pneumonia and also depend on (1) whether the site of parenchymal disease is the same or different with each episode and (2) whether the infiltrate is, on the one hand, dense, focal, and consolidated, or, on the other, atelectatic, patchy, diffuse, nodular, or interstitial. The specific approach to children whose pneumonia is associated with hospitalization, human immunodeficiency virus (HIV) infection, or some other form of immunologic deficiency is addressed in other chapters in this book.

Persistent or Progressive Pneumonia at a Single Site

Pathogen-Related Causes

Unresolved or untreated acute infection usually is responsible for persistent pneumonia (Table 35.1). In a patient receiving empiric antibiotic therapy, the cause is (1) infection by an organism not eliminated by the chosen antibiotic, either because of antimicrobial resistance of a common bacterial pathogen (penicillin-resistant *Streptococcus pneumoniae,* methicillin-resistant *Staphylococcus aureus* [MRSA], β-lactamase-producing *Haemophilus influenzae, Prevotella melaninogenica,* resistant gram-negative bacilli); or (2) more commonly, infection with organisms for which the chosen antimicrobial therapy was ineffective (*Mycobacterium tuberculosis, Mycoplasma pneumoniae, Chlamydophila* spp., *Coxiella burnetii, Francisella tularensis,* fungi, viruses, helminths).[11] Complications of appropriately treated bacterial pneumonia, such as necrotizing pneumonia, pleural effusion, and progression to lung abscess or empyema, or bronchiectasis also must be considered. The clinical, radiographic, and other imaging findings, as well as the context of the patient's illness, help prioritize possible causes (Fig. 35.1).

TABLE 35.1

Diagnostic Considerations for Pneumonia at a Single Site

Persistent or Progressive	Persistent or Recurrent
Untreated common acute infection **Segmental bronchiectasis** **Unresolved common acute infection** **Complication of acute infection** **Tuberculosis** **Uncommon infection**	**Atelectasis**
	Intraluminal obstructing lesions Foreign body Granuloma (infective or foreign body)
	Right middle lobe syndrome
	Bronchial tumor (adenoma, papilloma, lipoma)
	Extrinsic obstructing lesions
	Lymph nodes (infective or malignant)
	Tumor
	Enlarged heart, pulmonary arteries
	Vascular ring, sling
	Congenital abnormalities
	Bronchial anomalies (bronchomalacia, bronchial stenosis or web, tracheal bronchus)
	Tracheobronchial cysts (cyst adenomatoid malformation, lobar emphysema, bronchogenic cyst)
	Pulmonary sequestration

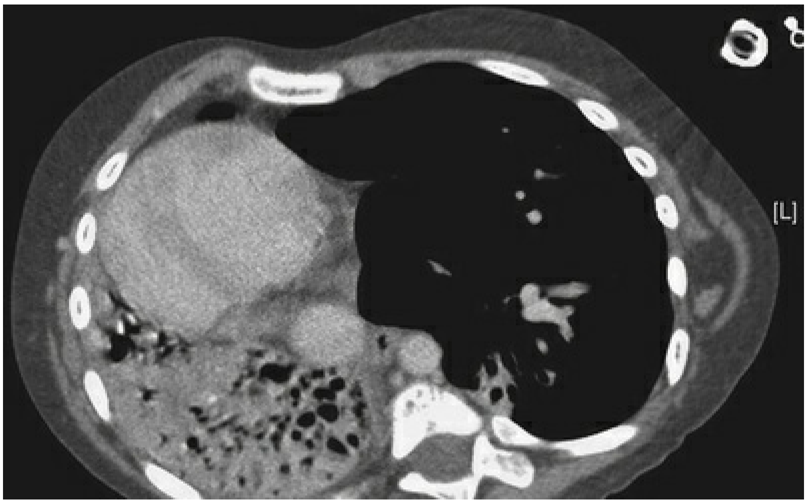

FIGURE 35.1 Computed tomography study of a 9-year-old boy with severe cerebral palsy, seizures, aspiration, and recurrent right lower lobe pneumonia showing severe bronchiectasis. Surgical resection was necessary. (Courtesy of J.H. Brien©.)

Tuberculosis always should be considered in children with persistent pneumonia or subacute presentation even if exposure is not obvious. Immigration from or travel to a region of the world with a endemic tuberculosis (Asia, Middle East, Africa, Latin America, countries of the former Soviet Union) or contact with individuals at high risk for tuberculosis (immigrants from regions in which tuberculosis is endemic; homeless persons; individuals with history of drug abuse or imprisonment; or persons with HIV infection) heightens the likelihood of tuberculosis.[12] A history of weight loss, cough, or fever is not always present. The radiographic abnormality generally is more impressive than the limited clinical findings, although occasional patients can manifest hectic fever, respiratory distress, and toxicity simulating acute pyogenic pneumonia. The presence of enlarged thoracic lymph nodes is a suggestive, but inconsistent, finding.

C. burnetii (Q fever) and *Chlamydia psittaci* infections are considered in patients with persistent fever, malaise, and myalgia, hacking cough, persistent parenchymal infiltrate, and exposure to farm animals or psittacine birds. Systemic illness usually overshadows pulmonary symptoms in young children with Q fever; psittacosis is rare in young children.

The likelihood of fungal pneumonia in a previously healthy child depends on place of residence or unusual environmental exposure.

Nodular or miliary densities are more common than lobar consolidation, but not consistently. *Histoplasma capsulatum* is endemic to the Midwest and to the St. Lawrence River valley in Canada. Subacute presentation with fatigue and a persistent cough is usual, and hilar lymphadenopathy is a clue. *Blastomyces dermatitidis* is a rare cause of persistent pneumonia in children. Endemic areas partially overlap those of histoplasmosis, including parts of the Mississippi, Ohio, Missouri, and St. Lawrence waterways. Older children with *Blastomyces* pneumonia may produce purulent sputum and often fail at least one course of treatment with an antibacterial agent before the etiology is identified correctly. *Coccidioides immitis* is endemic to the southwestern United States, including west Texas, Arizona, New Mexico, California, Utah, and Nevada, as well as northern Mexico and parts of Central and South America. Erythematous rashes and erythema multiforme are frequent early in the course, and erythema nodosum (also seen in *Blastomyces* or *Histoplasma* infection) can accompany pneumonia. Because environmental exposure often is a cause of fungal pneumonia, clusters of cases within the same family or in other persons exposed simultaneously can occur with *Histoplasma, Blastomyces,* and *Coccidioides* spp. infections. Rarely, a previously healthy child with or without undue exposure to dust, pigeon excreta, model terrarium, construction, or home renovation develops pneumonia due to *Cryptococcus* or *Aspergillus* spp. that leads to a protracted infection.

In adolescents at risk for HIV infection, *Pneumocystis jirovecii* should be considered, especially when persistent pneumonia is bilateral, interstitial, and associated with hypoxemia disproportionate to the severity of clinical illness or physical findings. Risk factors for HIV infection (injection drug use, multiple sexual partners, bisexual partner) need to be evaluated. In the infant with HIV infection, *P. jirovecii* pneumonia, especially when not properly treated, is rapidly progressive and has a high mortality.

Diffuse lower respiratory tract inflammation caused by some respiratory viruses can predispose to bacterial superinfection, especially in patients hospitalized with influenza or RSV infection requiring intensive care.[7] For children with laboratory-confirmed viral respiratory infection for whom symptoms persist or progress, a viral-bacterial coinfection deserves consideration. Several viruses, including influenza, can cause a rapidly progressive pneumonia nonresponsive to antibacterial therapy. Hantavirus can act similarly and also can involve other organs. Adenovirus can cause a necrotizing pneumonia (bronchiolitis obliterans).

Host-Related Causes

Multiple congenital or acquired anatomic abnormalities also are considered in children whose pneumonia (1) fails to resolve, (2) responds symptomatically to antimicrobial therapy but does not resolve radiographically, or (3) resolves and then recurs at the same site (see Table 35.1). Atelectasis (parenchymal volume loss) should be differentiated from persistent infiltrate or consolidation (without volume loss). Atelectasis occurs commonly with RSV bronchiolitis, airway hyperreactivity in infants and toddlers, asthma, and complete bronchial obstruction from intrinsic or extrinsic causes. Except with fixed obstructing lesions, atelectasis is expected to be transient or migratory; if atelectasis persists, the affected lung segment can become infected secondarily.

Bronchiectasis, with dilation of the bronchi, arises most commonly from damage to bronchial walls by infection or chronic inflammation. The bronchial wall then is susceptible to further dilation and distortion during breathing. Severe acute viral, bacterial, or fungal infection or recurrent infection related to CF, immunodeficiency, or local obstruction are known causes of bronchiectasis.[13] Adenovirus and measles virus infections, retained foreign body, and tuberculosis are associated most commonly with segmental bronchiectasis in the healthy host. In children with untreated or poorly controlled HIV infection or congenital immunodeficiency, lymphocytic interstitial pneumonia or recurrent bronchitis or pneumonia can progress to bronchiectasis.[14] After bronchiectasis has developed, impaired ciliary function and bronchial mechanics predispose to recurrent pneumonia. Children with extensive bronchiectasis often are fatigued easily, may have slower growth, and commonly have digital clubbing.

Intraluminal Obstructing Lesions

In otherwise healthy children, aspirated foreign body (or granulation tissue resulting from presence of a foreign body) is the most common cause of incompletely resolved or recurrent pneumonia at the same site.[1,15] The diagnosis is apparent if history of an event is elicited or a foreign body is visualized radiographically. Neither finding is present in most cases, but frequently older children remember the event after the object is retrieved at bronchoscopy. Spontaneous hemorrhage from the lower respiratory tract suggests foreign body (or pulmonary sequestration) and can be life-threatening.

Pneumonia at a single anatomic site can be related to particular positional vulnerability in children who are relatively immobile and who aspirate oropharyngeal material because of impaired neuromuscular function or coordination. A dependent segment or segments of lung are involved usually. Other intraluminal bronchial obstructions can cause associated single-site pneumonia, including bronchial adenoma, lipoma, papilloma, foreign body granuloma (e.g., peanut, other vegetable matter), granuloma of *M. tuberculosis* or nontuberculous *Mycobacterium* spp., or segmental bronchomalacia or bronchial stenosis.

The right middle lobe is predisposed to persistent atelectasis and subsequent infection or delayed resolution of pneumonia because of the acute angle and length of its bronchus, the proximity of its bronchus to hilar nodes, and poor to absent collateral ventilation compared with other regions of the lung. The right middle lobe also is a site of aspiration in the upright position. Recurrent right middle lobe pneumonia and atelectasis make up the so-called right middle lobe syndrome. Right middle lobe syndrome in children can have an intraluminal cause secondary to a primary ventilation disorder and chronic inflammation; asthma and foreign body aspiration are two such causes. Extraluminal compression from anatomic abnormalities and compression through lymph nodes from infectious causes, such as fungi and *M. tuberculosis,* also can be responsible. Evaluation of children with recurrent abnormalities of the right middle lobe should include bronchoscopy with direct visualization of the airway and sampling for cultures and cytology.[16]

Extrinsic Obstructing Lesions

Extrinsic airway compression most commonly is due to lymph node enlargement. Tuberculosis is most common, causing hilar, carinal, and other superior mediastinal airway compression, leading to secondary bacterial pneumonia. Pulmonary histoplasmosis, blastomycosis, and coccidioidomycosis also are important causes of hilar adenopathy.[1] Tumors can cause compression of the airway directly or through lymph node involvement. Congenital or acquired heart disease associated with an enlarged heart can cause compression of left lower lobe bronchus especially, leading to pneumonia. Shunting procedures that cause excessive pulmonary blood flow can lead to airway compression or segmental congestion and impaired drainage, predisposing to localized infection.

Congenital Abnormalities of the Respiratory Tract

Congenital abnormalities of airways, pulmonary parenchyma, or the diaphragm can cause localized persistent or recurrent pneumonia (Fig. 35.2). Tracheal bronchus, an abnormal bronchus arising from the trachea, leads to impaired drainage of the right upper lobe and persistent collapse. Congenital cystic anomalies of the tracheobronchial tree include congenital pulmonary airway malformation (CPAM; previously termed *congenital cystic adenomatoid malformation* or CCAM), congenital lobar hyperinflation, and bronchogenic cysts[17] (Fig. 35.3).

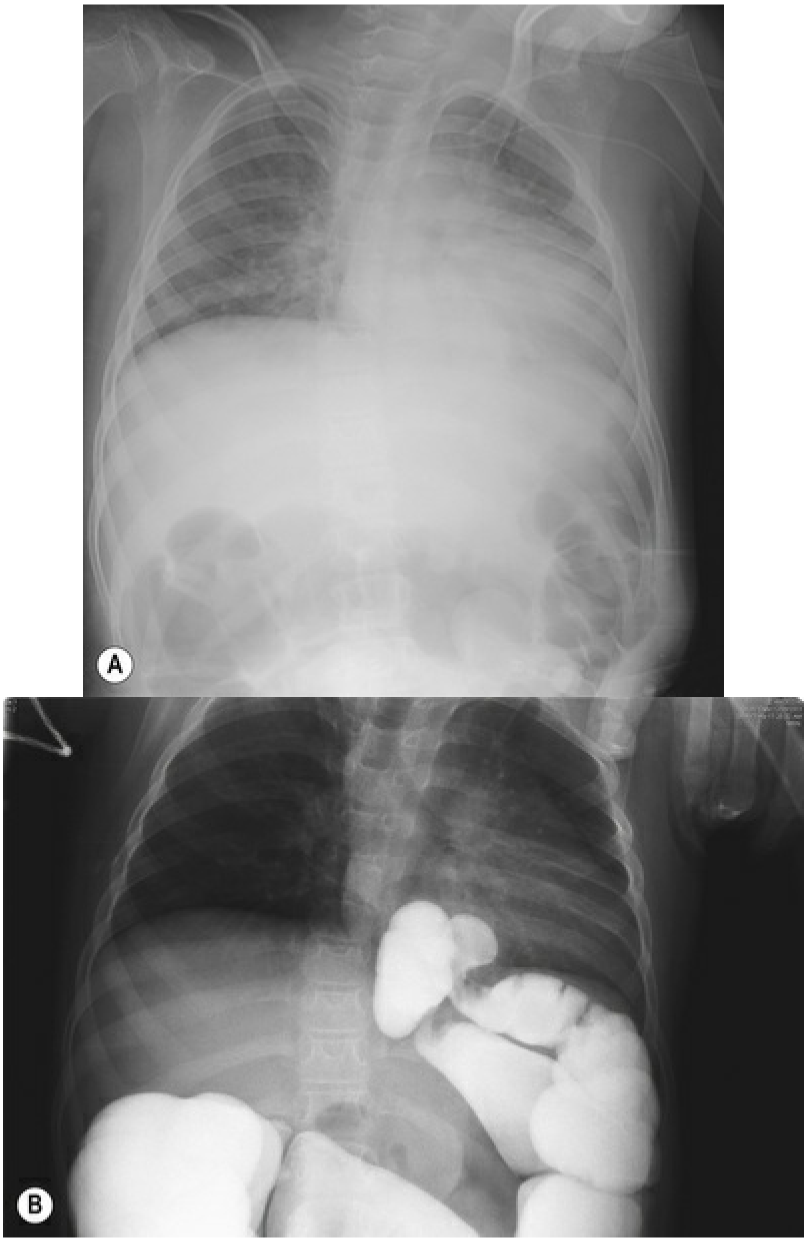

FIGURE 35.2 A 9-year-old girl with microcephaly had multiple episodes over multiple years of left lower lobe pneumonia (A) when barium study revealed congenital diaphragmatic hernia as the cause of persistent "consolidation" (B). (Courtesy of J.H. Brien©.)

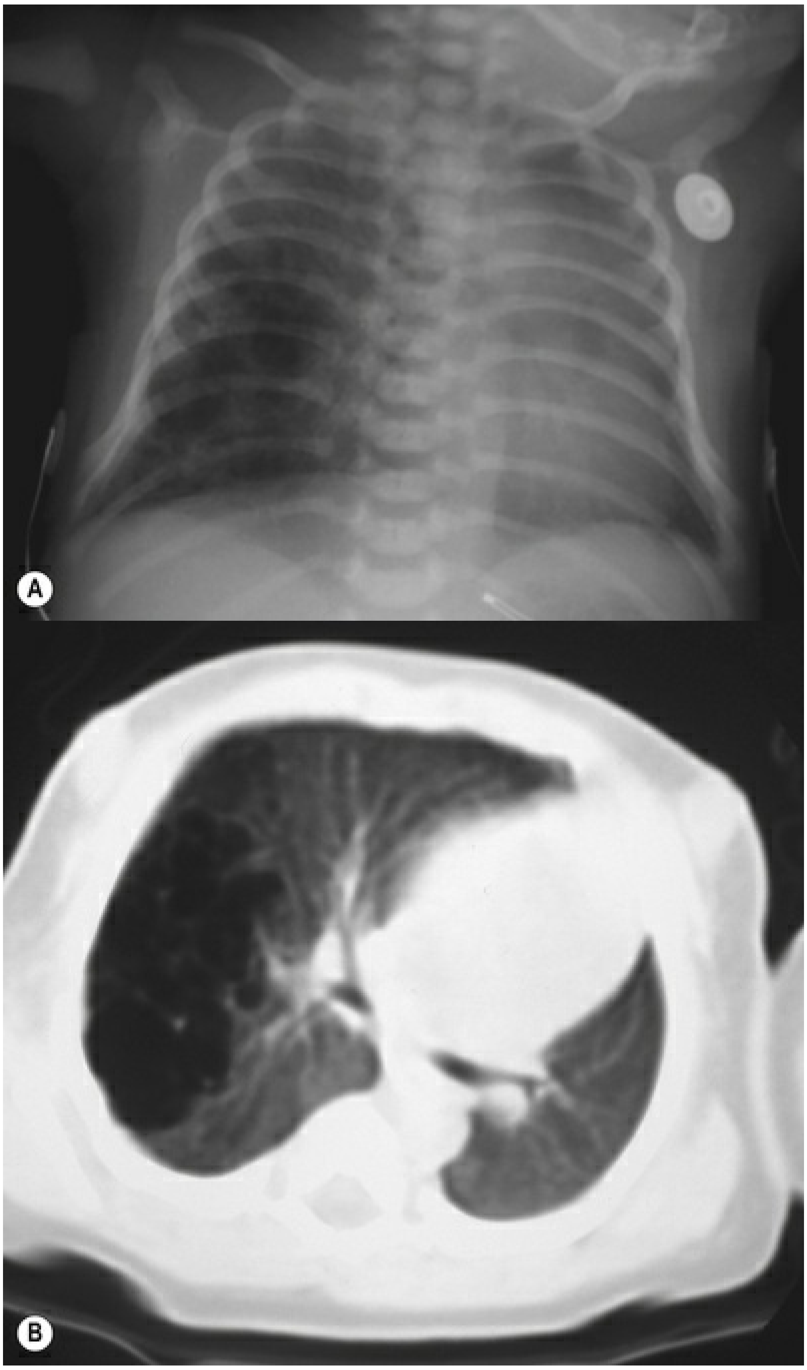

FIGURE 35.3 Congenital pulmonary airway malformation (previously termed *congenital cystic adenomatoid malformation*) in a term neonate who was evaluated because of respiratory distress. Plain radiograph (A) and lung window of axial computed tomography (B) show typical cluster of cysts, varying in size. Note superiority of computed tomography in demonstrating sites and extent of pathology. (Courtesy of E.N. Faerber.)

CPAM is the most common congenital lung anomaly, representing 30% to 40% of cases. CPAM and congenital lobar hyperinflation manifest early in infancy with respiratory distress (and cystic abnormality on radiographs) but can come to attention later as recurrent infection in the same segment of lung. Pulmonary sequestrations are the second most common congenital pulmonary anomaly and are composed of dysplastic pulmonary tissue that contains no connection or an aberrant connection to the tracheobronchial tree and receives a systemic vascular supply. Bronchogenic cysts are a form of foregut duplication cyst resulting from defective foregut budding. Bronchogenic cysts and pulmonary sequestrations, particularly intralobar sequestrations, can manifest as chronic or recurrent pneumonia later in childhood. Radiographically, bronchogenic cysts usually appear as round or oval well-circumscribed lesions typically in the paratracheal, hilar, and subcarinal areas. Pulmonary sequestrations appear as a focal opacity or mass in the lower lobe, usually on the left. With recurrent infection, intralesional necrosis can develop, and a more cystic appearance with or without air-fluid levels can be seen.[17]

Approach to Diagnosis

The history of illness, associated symptoms, environmental or contact exposures, judgment about adherence to prescribed therapy, possibility of partial improvement, and reevaluation of the appropriateness of prescribed therapy usually identify children with incompletely or inadequately treated uncomplicated acute pneumonia. Continued therapy or change in therapy with follow-up to document resolution is appropriate in many situations.

A tuberculin skin test, or for immunocompetent children 5 years and older, an interferon γ release assay (IGRA), should be performed. Because of their higher specificity and lack of cross-reaction with bacille Calmette-Guérin (BCG), IGRAs may be preferred in children 5 years and older who have received BCG.[18] In infants and young children, serial first-morning gastric aspirates are obtained for testing; these specimens may be superior to those obtained by bronchoscopy. Sputum is obtained from older children and adolescents. HIV testing is indicated for all individuals in whom tuberculosis is diagnosed.

Serologic tests for Q fever, psittacosis, mycoplasmal infection, histoplasmosis, coccidioidomycosis, or blastomycosis are useful when the setting and clinical findings are compatible. The diagnosis of histoplasmosis is improved by testing for both antibody and antigen.[19] Molecular-based methods, such as polymerase chain reaction assays, are available for some organisms. Fungal pneumonia due to *Candida, Cryptococcus,* or *Aspergillus* spp. can be difficult to diagnose. Serologic testing for cryptococcal and galactomannan antigen can be helpful. Bronchoalveolar lavage (BAL) usually is the next diagnostic specimen obtained for persistent pneumonia and has been reported to confirm the etiology of persistent pneumonia (including *Blastomyces* and *Histoplasma* spp., viruses, bacteria, and obstructing lesions) in 30% of immunocompetent children,[20] 27% of children with cancer,[21] and in 70% of children with acquired immunodeficiency syndrome (AIDS).[22]

If *P. jirovecii* pneumonia is suspected in an adolescent, diagnosis can be attempted through identification of the organism with methenamine silver staining of an induced sputum specimen. If the result is negative or a specimen cannot be obtained, BAL is performed. If *P. jirovecii* pneumonia pneumonia is confirmed, an underlying immunodeficiency must be sought.

Patients with documented recurrent pneumonia, segmental bronchiectasis, suspected anatomic or obstructing lesions, or pneumonia that persists beyond 8 weeks of appropriate therapy require further evaluation. Poor weight gain, weight loss, digital clubbing, polycythemia, or anemia validates a history of chronicity and the need to proceed aggressively. Bronchoscopy is performed to (1) exclude, or detect and remove, a foreign body; (2) detect extrinsic compression or intraluminal anomaly; (3) obtain a biopsy specimen of a mass; or (4) obtain a specimen for microscopy and culture.

Computed tomography (CT) is useful to evaluate more distal airways (including for bronchiectasis), mass lesions, tracheal bronchus, and congenital cystic anomalies and to define precise relationships of cysts with surrounding structures before surgical excision.[23,24] Additionally, CT is better than chest radiography to detect parenchymal lung complications (cavitary necrosis, abscess, bronchopleural fistula) and can better define pleural versus parenchymal disease.[25] For children with moderate to large parapneumonic effusions, imaging with chest ultrasound or CT is warranted to assess for loculation.[7] Multidetector CT with three-dimensional reconstruction generally is used for confirmation of pulmonary sequestration and presurgical planning.[17]

Persistent or Recurrent Pneumonia Not Confined to a Single Site

Causes of Dense Focal or Multifocal Infiltrates

Primary pulmonary as well as a variety of nonpulmonary disorders can predispose to a diagnosis of recurrent and persistent pneumonia affecting multiple areas of the lungs (Table 35.2). Primary pulmonary disorders include inflammatory diseases (such as asthma), congenital and acquired causes of epithelial dysfunction (ciliary dyskinesia, CF, viral infection), and congenital and acquired structural abnormalities (laryngeal and tracheal anomalies, chronic lung disease in infancy). Nonpulmonary disorders that cause pneumonia are myriad, comprising (1) conditions that impair or overcome normal pulmonary clearance mechanisms, such as impaired cough or gag reflex, neuromuscular disorders, and gastroesophageal reflux; and (2) conditions that increase the risk for infections in the lung, such as congenital and acquired immunodeficiency states and sickle cell hemoglobinopathies.

TABLE 35.2

Diagnostic Considerations for Recurrent or Chronic Pneumonia Not Confined to a Single Site

Dense Focal or Multifocal Infiltrates[a]	Diffuse Interstitial Infiltrates[b]
RESPIRATORY TRACT DISORDERS AND ASPIRATION	**MISCELLANEOUS CONDITIONS**
Asthma Cystic fibrosis Ciliary dyskinesia Bronchiolitis obliterans Recurrent aspiration (drugs, seizures, cricopharyngeal incoordination, neuromuscular disorders) Gastroesophageal reflux Laryngotracheal anomalies (laryngeal or submucosal cleft)	Bronchopulmonary dysplasia Pulmonary lymphangiectasia Hypersensitivity pneumonitis Allergic bronchopulmonary aspergillosis Vasculitis syndromes Desquamative interstitial pneumonitis Lymphocytic interstitial pneumonitis Histiocytosis Metastatic malignancies (neuroblastoma, Kaposi sarcoma)Alveolar proteinosis

Esophageal obstruction or dysmotility (webs, stricture, achalasia) Tracheoesophageal fistula Congenital abnormalities of heart and vessels **IMMUNOLOGIC ABNORMALITIES**[c] Agammaglobulinemia Common variable immunodeficiency Immunoglobulin G subclass deficiency Cellular immunodeficiency Complement deficiency Phagocytic defects Immunodeficiency secondary to disease or drug	Idiopathic pulmonary fibrosis Drug, chemotherapy, radiation, or physical agent (e.g., smoke inhalation, kerosene) injury
OTHER DISEASES	
Sickle cell disease	
Pulmonary hemosiderosis[b]	

[a] Most pneumonitis is infectious.

[b] Most pneumonitis is noninfectious.

[c] Infiltrates can also be diffuse interstitial or nodular, depending on pathogen.

Respiratory Tract Disorders and Aspiration

Asthma.

Many children referred for evaluation of recurrent pneumonia have asthma.[26] Asthma causes recurrent pulmonary atelectasis or infiltrates in children by inducing diffuse inflammation or mucous plugging of airways (Fig. 35.4); common manifestations include recurrent wheezing and cough.[26] Pulmonary densities that clear in hours or in a few days are likely to have been atelectasis rather than infectious pneumonia. Most asthma exacerbations are associated with occurrence of viral infections.[27] Nocturnal cough, protracted coughing after upper respiratory illnesses, and, even if not acutely ill, exercise-induced cough are important historical clues to asthma, especially in older children. Wandering atelectasis, segmental overaeration, and nonconsolidated, perihilar, peribronchial, and interstitial infiltrates are helpful radiographic clues that asthma is the underlying cause. In patients with these features, asthma is far more likely than an underlying cause of presumed recurrent infectious pneumonia in children.[28,29]

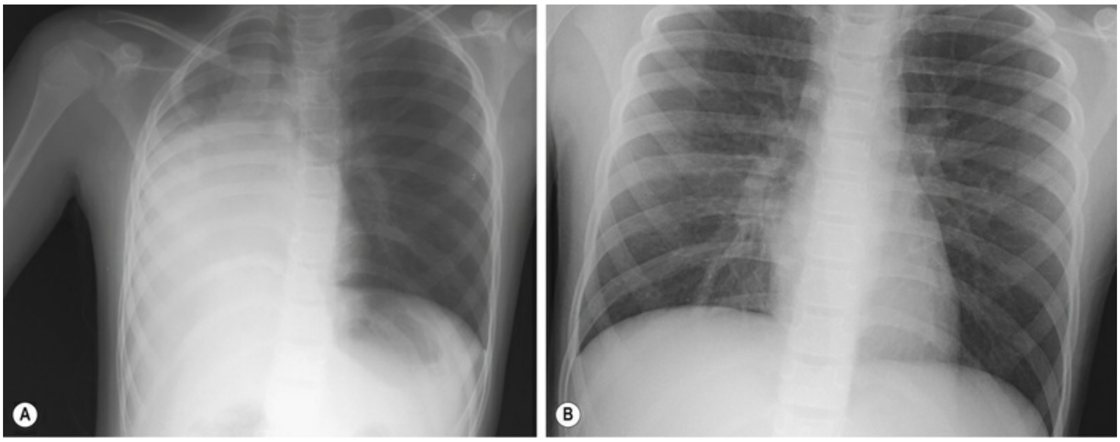

FIGURE 35.4 A 9-year-old girl with asthma was hospitalized for treatment of “pneumonia.” Chest radiograph on admission shows dense right lung consolidation (A). Note decreased volume of right side of chest with deviation of trachea and heart to the right, suggesting atelectasis. Chest radiograph 2 days later, following chest physical therapy and treatment of asthma (B). Course is most compatible with mucus plug. (Courtesy of J.H. Brien©.)

Cystic Fibrosis.

CF is characterized by early colonization and infection of the airways.[30] Functional deficiency of the CF transmembrane conductance regulator causes deficient chloride and bicarbonate secretion into airway secretions. Loss of the critical hydration of the airway surface liquid and mucus layer leads to chronic retention of pathogens in the lower airways and a secondary inflammatory response. Classical pathogens causing chronic suppurative infection are *Pseudomonas aeruginosa*, *Burkholderia cepacia*, and *S. aureus* and, now, MRSA. Emerging pathogens include nontuberculous mycobacteria, *Achromobacter* spp., and *Stenotrophomonas maltophilia*.[31] Chronic cough, poor weight gain, digital clubbing, sinusitis, and nasal polyposis at a preadolescent age are distinctive characteristics. Chest radiographs can be abnormal in infancy and are never normal again, with multiple persistent and new areas of parenchymal consolidation, overinflation, and eventual bronchiectasis. All states in the United States perform newborn screening for CF, and measurement of sweat chloride concentration remains the primary test for the confirmation of the diagnosis of CF.

Primary Ciliary Dyskinesia.

Primary ciliary dyskinesia, also called *immotile cilia syndrome*, is a rare disease characterized by congenital impairment of mucociliary clearance. Originally described as the Kartagener triad, consisting of dextrocardia, sinusitis, and bronchiectasis, ciliary dyskinesia leads to recurrent sinopulmonary infections. Clinical features include neonatal respiratory distress (82%), chronic cough (99%), chronic nasal congestion (97%), and chronic or recurrent otitis media (92%).[32] The chronic cough and nasal congestion begin at a median of 1 month of age. Laterality defects (situs inversus totalis and heterotaxy) occur in 55% of patients, and chest CT reveals prominent bronchiectasis (median of 3 involved lobes) and alveolar consolidation (median of 2 involved lobes).[32] Although limited to specialized centers, measurement of nasal nitric oxide is a useful screening test for patients 5 years and older with a clinical suspicion of primary ciliary dyskinesia.[33] Diagnosis is confirmed by high-speed videomicroscopy and electron microscopy of specimens of respiratory tract columnar cells obtained by nasal brush biopsy. Samples should be obtained when the patient is not infected acutely.

Epithelial Damage.

Damage of epithelium due to infection by viruses, *Bordetella pertussis,* and *M. pneumoniae* can lead to impairment of defense mechanisms and recurrent pneumonia.[34] Additionally, exposure to cigarette smoke and other environmental pollutants impairs ciliary function.

Bronchiolitis Obliterans.

Bronchiolitis obliterans is a chronic lung disease, which in most cases in children follows lower respiratory tract infection, usually caused by adenovirus. The incidence is highest when children are infected between 6 months and 2 years of age. Certain populations of Native Americans and Maoris (New Zealand) have a higher incidence of chronic lung disease after pulmonary adenovirus infection in childhood. Bronchiolitis obliterans also occurs after inhalation of various acids, as a late complication after lung transplantation, and in bone marrow transplant recipients associated with graft-versus-host disease. Bronchiolitis obliterans organizing pneumonia arises from masses of granulation tissue in alveolar ducts that obliterate airspaces. Dyspnea and cough, combined obstructive and restrictive functional abnormalities, radiographic hyperaeration, and airspace consolidation, are typical. In occasional cases, the obliterative process is confined to one lung, which then can result in unilateral hyperlucent lung or Swyer-James syndrome. Patients with bilateral, diffuse obliterative disease often have pulmonary edema. Although the clinical course, chest radiograph, and CT are suggestive, the diagnosis is confirmed by lung biopsy.[35]

Neurologic Dysfunction.

Neurologic dysfunction with associated aspiration is the most common identified cause of recurrent pneumonia.[8,29,36] Dysfunction predisposes to pneumonia as a result of pharyngeal incoordination or muscle weakness, which leads to failure of the gag, cough, or swallow reflex to protect the airway. Lesions of upper motor neurons, seizures, and decreased level of consciousness are common predisposing conditions. Pneumonia tends to occur in dependent lobes (e.g., the middle lobe or lung bases when aspiration occurs in the upright position, and the upper lobes when in the supine position). Fluoroscopic examination during a barium meal can be performed to examine upper pharyngopalatal coordination. Although gastric fundoplication and placement of a gastrostomy tube frequently are performed in such patients for feeding, the aspiration of oropharyngeal secretions (antegrade aspiration) continues. Chronic pulmonary aspiration results in progressive pulmonary disease, bronchiectasis, and respiratory failure eventually. Chronic pulmonary aspiration is the leading cause of death in children with severe neurologic disorders.[37] Radionuclide salivagram is a useful test to detect antegrade pulmonary aspiration.[38,39]

Gastroesophageal Reflux Disease.

Gastroesophageal reflux disease (GERD) can cause pneumonia in infants by spillover of gastric acid, particulate matter, or both into the trachea. A history of postprandial emesis, irritability accompanied by arching of the back (Sandifer syndrome), and stridor are recognized manifestations, and notable is the temporal association between feeding and respiratory symptoms.[8] In a series of hospitalized children, recurrent pneumonia from aspiration in association with GERD came to attention at a mean age of 1.4 years.[8] Esophageal pH monitoring is a valid measure of esophageal acid exposure and may be useful to correlate symptoms (e.g., cough) with acid reflux episodes and to select those patients with wheezing or respiratory symptoms in whom GERD is an aggravating factor.[40] Combined impedence and pH monitoring has the advantage of detecting non–acid reflux (e.g., patients taking proton pump inhibitors) in addition to acid reflux and is superior to pH monitoring alone for evaluation of the temporal relationship between symptoms and GERD.[40,41] A barium swallow study is not useful for the diagnosis of GERD but is useful for the evaluation of anatomic abnormalities.[40] Nuclear scintigraphy (milk scan) may have a role in the diagnosis of pulmonary aspiration in patients with chronic and refractory respiratory symptoms, but a negative test does not rule out possible pulmonary aspiration of refluxed material.[40] Children with recurrent aspiration related to GERD are generally considered most likely to benefit from antireflux surgery when medical therapy fails, but additional study is required to confirm that.[40]

Congenital Anomalies.

H-type tracheoesophageal fistula is a rare developmental abnormality that can escape recognition in the neonatal period and manifest later as recurrent pneumonia. Respiratory distress with feeding is typical. Radiographic demonstration of caudad-to-cephalad fistula to the trachea during retrograde filling of the esophagus with water-soluble contrast is diagnostic. By 1 year after anastomosis in infants with esophageal atresia or tracheoesophageal fistula, 39% developed esophageal stricture and 3.3% recurrent fistula,[42] which predisposes them to recurrent pneumonia from aspiration. Within 2 years of patient discharge after esophageal atresia repair with or without tracheoesophageal fistula, 12.7% were readmitted with pneumonia.[43] Clues to other congenital anomalies of the trachea, great vessels, or esophagus that cause recurrent pneumonia are usually present in associated symptoms or signs (positional respiratory distress, cough, stridor, feeding disorders).

Ventilator-Associated Pneumonia.

Ventilator-associated pneumonia (VAP) is defined as a healthcare-associated pneumonia based on clinical, radiologic, and microbiologic criteria in ventilated patients[44] (see Chapter 99). VAP is the most common infection occurring in mechanically ventilated patients. Bacteria that colonize the oropharynx can evade host defenses more easily in the presence of endotracheal intubation or tracheostomy tube and neuromuscular blockade or dyscoordination. *P. aeruginosa, Staphylococcus aureus* (including MRSA), enteric gram-negative bacilli, and nontypable *H. influenzae* are the most frequently recovered organisms.[45,46] Reported incidences of VAP varied widely and reflect the absence of a diagnostic gold standard and lack of specificity of current diagnostic methods.[46,47] Microbiologic specimens obtained by BAL have greater diagnostic accuracy compared with tracheal aspirate cultures.[46] Tracheal aspirate Gram stains and cultures do not appear to distinguish between infection and colonization.[47] Implementation of a sustainable prevention bundle focusing on prevention of aspiration and bacterial colonization resulted in a reduced rate of suspected VAP.[45] Prevention of pneumonia in children ventilated outside of the hospital continues to be challenging.

Immunologic Abnormalities

Immunologic abnormalities constitute an uncommon cause of recurrent pneumonia. The characteristic pattern of pulmonary involvement is recurrent, dense focal infiltrates at different sites, but diffuse interstitial or alveolar and interstitial infiltrates can occur, depending on the pathogen and defect. Qualitative or quantitative defects in phagocytic function, immunoglobulin synthesis, cellular immune function, or complement activity can lead to recurrent pneumonia.[1,8,26,29,36] The etiologic agents of pneumonia and involvement of the sinopulmonary system exclusively, or in concert with other organ involvement, predict the presence and type of immune defect.

Immunoglobulin and Complement Deficiency.

Recurrent pulmonary infections caused by encapsulated organisms such as *S. pneumoniae* and *H. influenzae* suggest a quantitative or qualitative abnormality in immunoglobulins. Nontypable *H. influenzae, S. aureus,* and *P. aeruginosa* also are pulmonary pathogens associated with X-linked agammaglobulinemia and other antibody deficiency syndromes and chronic obstructive lung disease due to frequent aspiration. Dysfunctional hypergammaglobulinemia of HIV infection is associated with sinopulmonary and invasive infection due to *S. pneumoniae* and other encapsulated organisms. Complement deficiency, although rare, can predispose to recurrent pulmonary pyogenic infection.

Phagocytic Cellular Defects.

Abnormalities in the number or function of phagocytic cells predispose to recurrent pyogenic infection, including pneumonia. Recurrent skin and soft tissue infections, and other invasive infections, also occur commonly. The most common neutrophil disorder resulting in recurrent infections is chronic granulomatous disease (CGD), a genetic immunodeficiency characterized by defective phagocyte respiratory burst and superoxide production. In the national registry of CGD patients, 80% had at least one episode of pneumonia.[48] Infections are caused by catalase-producing organisms and can be a clue to the defect. *Aspergillus* spp., *B. cepacia*, *Nocardia* spp., *Serratia marcescens,* and *S. aureus* are the most common causes of pneumonia in patients with CGD.[48,49] Fungal infection is a major determinant of survival.

Cellular Immune Defects.

Abnormalities of T lymphocytes, such as those due to severe combined immunodeficiency, DiGeorge (22q11.2 deletion) syndrome, HIV infection, or immunodeficiency secondary to disease or therapeutic agents, predispose to recurrent, progressive, and persistent infections, frequently pneumonia. Patients with ataxia-telangiectasia can develop interstitial lung disease, even in the absence of infection. Progressive disseminated viral, fungal, or mycobacterial infection and *P. jirovecii* pneumonia are suggestive of cellular immune defects.

Other Conditions

Acute thoracic, bony infarction or pulmonary infarction in a patient with sickle cell hemoglobinopathy can lead to the “acute chest syndrome,” which can be difficult to distinguish from pneumonia and commonly is precipitated or complicated by pneumonia (see Chapter 106). Idiopathic pulmonary hemosiderosis can masquerade as recurrent pneumonia with diffuse pulmonary infiltrates. Diagnosis is made by clinical features (rapid onset and resolution of symptoms and parenchymal pulmonary infiltrate, usually without fever) and bronchoscopy, with BAL showing hemosiderin-laden macrophages. Cow milk protein allergy, environmental (*Stachybotrys* fungi), genetic, and autoimmune conditions have been postulated as causes of idiopathic pulmonary hemosiderosis. A review of a series of 25 patients supported the role of autoimmunity and genetic factors.[50]

Causes of Diffuse Interstitial Infiltrates

A variety of noninfectious entities cause chronic or recurrent lower respiratory tract symptoms and diffuse interstitial or alveolar infiltrates on chest radiographs that can be difficult to distinguish from pneumonia (see Table 35.2). Childhood interstitial lung disease describes a heterogeneous group of rare chronic respiratory disorders in children, particularly younger than 2 years, which includes growth and developmental abnormalities as well as immunologic problems. These disorders have variable lung pathology associated with poor gas exchange.[51] The term *diffuse lung disease* often has been used interchangeably. Typical features are progressive cough, dyspnea, tachypnea, and crackles in the presence of diffuse infiltrates on radiography or CT. Diagnostic evaluation includes pulmonary function tests, high-resolution chest CT, genetic testing for surfactant disorders, and lung biopsy.

Cardiac abnormalities leading to recurrent pulmonary symptoms and radiographic abnormalities include congestive heart failure, anomalous pulmonary venous return, and congenital or acquired inequality of pulmonary artery blood flow. Congenital lymphangiectasia or pulmonary veno-occlusive disease can be misdiagnosed as recurrent pneumonia or pulmonary edema. Idiopathic or autoimmune disorders that cause infiltrates include hypersensitivity pneumonitis, allergic aspergillosis, sarcoidosis, vasculitis syndromes, granulomatosis with polyangiitis (Wegener granulomatosis), and Goodpasture syndrome. Reticulonodular infiltrates suggest a differential diagnosis that includes *M. pneumoniae* infection, *P. jirovecii* infection, HIV-related lymphoid interstitial pneumonitis, Kaposi sarcoma, histiocytosis, metastatic neuroblastoma, and lymphoma.

Approach to Diagnosis

Clues from history, physical examination, growth and development, radiographic pattern, and confirmed causes of pneumonia or other infections should guide investigation and permit a staged evaluation.[28,52,53] For example, stridor suggests tracheal anomalies; chronic cough productive of purulent sputum suggests bronchiectasis possibly due to disorders of antibody or phagocytic function, CF, or ciliary dyskinesia; severe and complicated sinusitis or otitis media suggests antibody deficiencies or ciliary dyskinesia; wheezing commonly indicates asthma but can be present in a variety of respiratory tract disorders (e.g., foreign body, CF, bronchiolitis obliterans). A history of recurrent problems confined exclusively to the respiratory tract makes cellular immune defects and phagocytic defects unlikely. Infections involving other organ systems, such as recurrent boils or soft tissue abscesses, raise the possibility of phagocytic defects.

Confirmation of specific infectious agents heightens suspicion of certain disorders. Examples of sentinel organisms are catalase-producing agents for CGD; *P. aeruginosa* for CF; *B. cepacia* for CF and CGD; and *P. jirovecii* for cellular defects and HIV infection.

A complete blood count is used to assess anemia or polycythemia; abnormal numbers, appearance, or differential makeup of leukocytes; and thrombocytopenia (associated with immunologic disorders such as Wiskott-Aldrich syndrome, primary hematologic cytopenias, or suppression by disseminated virus infection) or thrombocytosis (associated with an inflammatory response). A tuberculin skin test or an IGRA for children 5 years or older generally should be performed, particularly but not only if there are risk factors for tuberculosis.

An underlying medical condition was identified in 86% to 92% of children with recurrent pneumonia in two series.[8,36] In a third series that excluded children with wheezing, 31% of patients did not have an underlying cause identified.[29] Asthma often is diagnosed in children referred for recurrent “pneumonia.” In many cases the preceding episodes of pneumonia are not true lobar consolidations with fever but rather focal abnormalities on physical examination or chest radiograph that occur with an asthma exacerbation.[53] Clues to the diagnosis of asthma include the presence of atopy in the patient, a family history of asthma or atopy, prior response to a bronchodilator or corticosteroid, predominance of wheezes and rhonchi, and rapid resolution of radiographic abnormality (which usually is atelectasis rather than infiltrate).

In three retrospective series of children with recurrent pneumonia, the most common identified cause was aspiration, particularly in children with underlying neurologic or neuromuscular disorders.[8,29,36] A pattern of pneumonia in dependent pulmonary segments suggests aspiration. For other patients, certainly those with impaired growth or digital clubbing and those with radiographs showing lobar or segmental infiltrates, thoracic adenopathy, or bronchiectasis, a specific diagnosis must be pursued. Testing for CF should be performed routinely. If infections are confined to the respiratory tract in infants, a barium swallow study is a useful early test to assess for anatomic anomalies such as vascular rings, duplication cysts, and tracheoesophageal fistulas. Further diagnostic tests, including combined impedence and pH monitoring, CT, magnetic resonance imaging, and nuclear medicine scans (salivagram, milk scan), are selected according to the likely etiology. Measurement of nasal nitric oxide and evaluation of a nasal or bronchial biopsy to assess ciliary structure and function should be considered if the child has a documented history of recurrent sinusitis, otitis media, and pneumonia, especially when bronchiectasis is present.

Although immunologic defects are not common, when suspected, screening tests should include testing for HIV, quantitative measurement of immunoglobulins (IgG, IgA, IgM, and IgE), complement hemolytic activity assay, and functional white blood cell tests, such as dihydrorhodamine flow cytometric assay for CGD. Measurement of specific antibody responses to proteins (tetanus IgG antibody) and polysaccharide antigens (IgM isohemagglutinins and prepneumococcal and postpneumococcal polysaccharide vaccination IgG antibodies in children 2 years and older) are more reliable measurements for B-lymphocyte function than the quantity of immunoglobulins. Flow cytometry for lymphocyte enumeration and mitogen proliferation assays assess cell-mediated immune function.

Bronchoscopy with BAL (or in older, larger children obtaining a protected brush specimen) can confirm underlying conditions and specific infectious causes of pneumonia. Lung biopsy is the definitive test required to establish the etiology or pathophysiology of many causes of chronic, recurrent pneumonia when specific pathogens are not otherwise confirmed, especially when the pattern of involvement is interstitial and a noninfectious cause is suspected.

Key Points

Persistent and Recurrent Pneumonia

Definitions and Epidemiology

- Persistent pneumonia is defined as continuation of symptoms and radiographic findings beyond 4 weeks after onset.
- Recurrent pneumonia is the occurrence of ≥2 episodes of pneumonia in a 1-year period or ≥3 episodes in any period, with radiographic resolution between episodes.
- Approximately 8% of patients hospitalized with pneumonia have recurrent pneumonia.

Clinical Features

- Unresolved or untreated acute pneumonia progresses to persistent pneumonia.
- Often patients referred for “recurrent pneumonia” have a history of recurrent wheezing and have asthma, frequently with transient atelectasis.

- Many patients with recurrent pneumonia have a known predisposing condition such as neurologic or neuromuscular disorders leading to aspiration.

Diagnosis

- Pathogen-related causes (e.g., tuberculosis, fungal) and host-related causes (intraluminal or extraluminal obstruction, congenital lung anomalies) must be considered for patients with persistent pneumonia.
- Involvement of one area of the lung (e.g., foreign body aspiration, congenital pulmonary airway malformation, sequestration) versus multiple areas (asthma, aspiration, cystic fibrosis, immunologic disorders) influences the evaluation for both persistent and recurrent pneumonia.
- Specific diagnostic testing should be guided by the following:

▪ Involvement of other organ systems such as sinusitis with cystic fibrosis, immunodeficiencies, or primary ciliary dyskinesia

▪ Gastrointestinal involvement with cystic fibrosis

▪ Feeding difficulties with gastroesophageal reflux disease

▪ Leukopenia with cell-mediated defects

- Isolation of specific or sentinel organisms (e.g., catalase-positive organisms with chronic granulomatous disease, or *Pseudomonas aeruginosa* and *Burkholderia cepacia* with cystic fibrosis) also helps guide diagnostic testing.

Pneumonia in the Immunocompromised Host

Marvin B. Harper, Grace M. Lee, Kenneth McIntosh

Pneumonia is a common disease in naturally occurring states of immunologic incompetency, such as congenital immunodeficiencies, malnutrition, and human immunodeficiency virus (HIV) infection, as well as in iatrogenically induced immunodeficiency, as occurs during chemotherapy for cancer, during treatment of rheumatologic diseases, or after tissue transplantation. The clinical findings are diverse, the potential for extended morbidity and mortality is great, and there is a broad range of causative microorganisms.

Etiologic Agents and Epidemiology

The etiologic agents of pneumonia in the immunocompromised host consist not only of the same agents that cause pneumonia in the immunocompetent host but also of a large number of opportunistic agents. The importance of agents in various forms of immunologic incompetence depends on the particular part of the immune system that is deficient and on the part of the immune system that is normally critical in defense against that microorganism (Table 36.1).

TABLE 36.1

Microorganisms Associated With Severe Pneumonia in Immunodeficiency States

Deficiency	Viruses	Pyogenic Bacteria	Mycobacteria	Fungi
B-lymphocyte deficiency	Enteroviruses Adenoviruses	*Streptococcus pneumoniae* *Haemophilus influenzae* Meningococcus	None	None
T-lymphocyte deficiency (including tumor necrosis factor-α deficiency)	Varicella-zoster virus Rubeola virus Herpes simplex virus Cytomegalovirus Adenovirus Respiratory syncytial virus Parainfluenza virus Human metapneumovirus	*Neisseria meningitidis* *Listeria monocytogenes* *Pseudomonas aeruginosa* *Stenotrophomonas* spp. *Burkholderia* spp. *Legionella* spp. Other opportunistic bacteria	*Mycobacterium tuberculosis* *Mycobacterium avium* complex *Mycobacterium fortuitum* Calmette-Guérin bacillus Other opportunistic mycobacteria	*Pneumocystis jirovecii* *Candida albicans* *Cryptococcus neoformans* *Nocardia* spp.
Neutrophil dysfunction	None	*Staphylococcus aureus* *Burkholderia cepacia* *Serratia marcescens*	*Mycobacterium tuberculosis* Calmette-Guérin bacillus Nontuberculous mycobacteria	*Aspergillus* spp. *Nocardia* spp. *Candida* spp.
Neutropenia	None	*Pseudomonas aeruginosa* *Stenotrophomonas* spp. *Burkholderia* spp. Other opportunistic bacteria	None	*Aspergillus* spp. *Pseudallescheria boydii* Agents of mucormycosis

In conditions in which the normal quantities of functional antibody are deficient, such as hypogammaglobulinemia,[1] or in the functional B-lymphocyte deficiency that accompanies HIV infection in infants and children,[2] bacterial pneumonias are common. Pneumonia largely is caused by *Streptococcus pneumoniae,* various species of *Haemophilus,* and other encapsulated bacteria. Pneumonia due to respiratory viruses is not more frequent or more severe in antibody deficiency states.

In conditions of relatively pure deficiency in cell-mediated (lymphocyte) immunity, such as severe malnutrition, the late stages of AIDS, and some congenital immunodeficiencies, certain viral infections are life-threatening and require careful prophylaxis and potent treatments. These viruses include the herpesviruses, especially cytomegalovirus, varicella-zoster virus (VZV), herpes simplex virus (HSV), and, occasionally, human herpesvirus 6 (HHV-6),[3] all of which are unusual causes of clinically significant pneumonia in healthy children. In areas of the world where measles remains endemic, pneumonia is a common complication of infection in the malnourished child and can be severe. Common respiratory viruses, particularly respiratory syncytial virus (RSV), parainfluenza viruses, human metapneumovirus, and adenovirus, can cause prolonged, severe life-threatening infection.[4–6] Lymphocyte deficiencies also predispose to pneumonia due to many bacteria (see Table 36.1) as well as several fungi, including *Pneumocystis jirovecii.*

Epstein-Barr virus (EBV) is a special case. A form of subacute pneumonia characterized by micronodules of proliferating lymphoid tissue, known as *lymphocytic interstitial pneumonitis* (LIP), frequently (although not exclusively) is associated with EBV infection in several states of immunologic dysregulation, particularly in untreated children with HIV infection between 18 months and 6 years of age.[7–9] LIP usually manifests as a slowly developing, afebrile pulmonary disease associated with progressive hypoxia and generalized lymphadenopathy, with characteristic diffuse micronodular infiltrates apparent on chest radiography (see Chapter 112, Fig. 112.3).

In states of neutrophil dysfunction or profound neutropenia, an entirely different spectrum of organisms is commonly implicated in pneumonia. In chronic granulomatous disease and pure neutropenia, pneumonia is frequently caused by *Staphylococcus aureus* (including methicillin-resistant strains) and opportunistic bacteria and fungi such as *Pseudomonas aeruginosa, Burkholderia cepacia, Nocardia* spp., *Mycobacterium tuberculosis* (particularly in areas where it is widespread[10]), nontuberculous mycobacteria, and *Aspergillus* spp.[11] Neutropenia alone does not appear to predispose to either viral or *Pneumocystis* pneumonia (PCP).

Defects in innate immunity, either genetic or drug-induced, add complexity to susceptibilities. IRAK4 and MYD88 deficiencies manifest much like B-lymphocyte defects, with frequent pyogenic pneumonias in childhood.[12] Common genetic polymorphisms in the mannose-binding lectin gene may contribute to susceptibility to opportunistic pneumonias in the posttransplantation period.[13] Innate immunity also can be inhibited pharmacologically, and drugs that block tumor necrosis factor-*α* predispose to mycobacterial and fungal infections as well as other infections for which cellular immunity is important.[14]

Immunodeficiencies that are drug induced, particularly those that occur during cancer chemotherapy or after organ or stem cell transplantation, are complex. These include drug-induced compromise of the oral and intestinal mucosal barriers, neutropenia or neutrophil dysfunction, and defective lymphocyte function. In this setting, pneumonia commonly is due to opportunistic bacteria and fungi, acquired nosocomially or from resident mucosal flora, such as *P. aeruginosa* and *Stenotrophomonas maltophilia;* α-hemolytic streptococci and other oral bacteria; *Nocardia, Candida,* and *Aspergillus* spp.; and other yeast and filamentous fungi.[15–17] Children undergoing cancer chemotherapy or solid organ transplantation may have normal antibody levels (native or infused) but are nonetheless at increased risk for infections due to encapsulated bacteria because the defense against microorganisms is multifaceted and mixtures of drug-induced lymphocyte and neutrophil dysfunction among these children are common.[18,19]

The most common viral infections in these drug-induced immunodeficiency states are those that cause pneumonia in children with pure lymphocyte deficiencies: cytomegalovirus (CMV), VZV, HSV, and, in endemic areas, rubeola.[20,21] Viruses that commonly cause pneumonia in healthy hosts, such as RSV, influenza, parainfluenza viruses, human metapneumovirus, and adenovirus, display greater virulence in both children and adults after solid -organ or human stem cell transplantation, particularly when cellular immunity is profoundly suppressed.[22–29] In the posttransplantation setting, EBV can cause progressive pulmonary disease, but this is usually in the form of posttransplantation lymphoproliferative disease, with enlarging masses of lymphoid tissue in the mediastinum and parenchyma of the lung rather than diffuse LIP, as was described earlier.[30]

Because patients with iatrogenically imposed states of immunodeficiency tend to spend long periods in the hospital, organisms that cause significant pneumonia in such patients often are nosocomially acquired. In addition, they reflect the epidemiology and antimicrobial resistance patterns of healthcare-associated organisms, whether through carriage on the hands of caregivers (e.g., methicillin-resistant *S. aureus* or multidrug-resistant gram-negative enteric organisms), through the hospital's water supply (e.g., *Legionella* species), through the spread of small-particle aerosols (e.g., *Aspergillus* spp.), or because these patients often receive antimicrobial agents that alter normal bacterial flora, creating a void or niche for other more antibiotic-resistant bacteria to flourish.

The frequency and reported cause of pneumonia after solid-organ transplantation vary greatly by transplantation center and the organ transplanted. Nonetheless, certain etiologic patterns emerge. CMV pneumonia occurs in 12% to 45% of renal,[19] liver,[31,32] lung,[33] and allogeneic hematopoietic stem cell transplant recipients.[34,35] Risk is highest among CMV-negative recipients from CMV-positive donors for solid-organ transplantations, whereas risk is highest among CMV-positive recipients from CMV-negative donors for hematopoietic stem cell transplantations. Risk also is increased among patients with graft-versus-host disease who require higher degrees of immunosuppression. Anticipatory strategies[36] or prophylaxis with ganciclovir or valganciclovir have reduced but not eliminated CMV pneumonia.[37,38] Nosocomially acquired viruses and bacteria remain major causes of pneumonia among transplant recipients.[31–35,39,40] *Aspergillus* has been identified as the cause of up to 35% of pneumonia cases after bone marrow or solid-organ transplantation, although its incidence may decrease with increased use of antifungal prophylaxis.[19,31–35,39,40] There is high risk for tuberculosis after renal transplantation in endemic areas.

The causes of pneumonia and of other infections often follow a temporal pattern specific to the chemotherapy used or tissue transplanted. For example, after solid-organ transplantation, nosocomially acquired bacteria predominate as a cause of pneumonia in the first month; later, viruses, especially CMV and adenovirus, and to a lesser extent *Listeria, Nocardia,* and *Aspergillus* spp., may be the cause. More than 6 months after solid-organ transplantation, the agents of community-associated bacterial pneumonia become more common.[41] After hematopoietic stem cell or marrow transplantation, the risk for *Aspergillus* infection is bimodal, with peak incidence at less than 40 days, followed by a second peak occurring more than 100 days after transplantation. The first peak likely is related to neutropenia, and the later peak likely is related to use of high doses of corticosteroids for the treatment of graft-versus-host disease.[42,43]

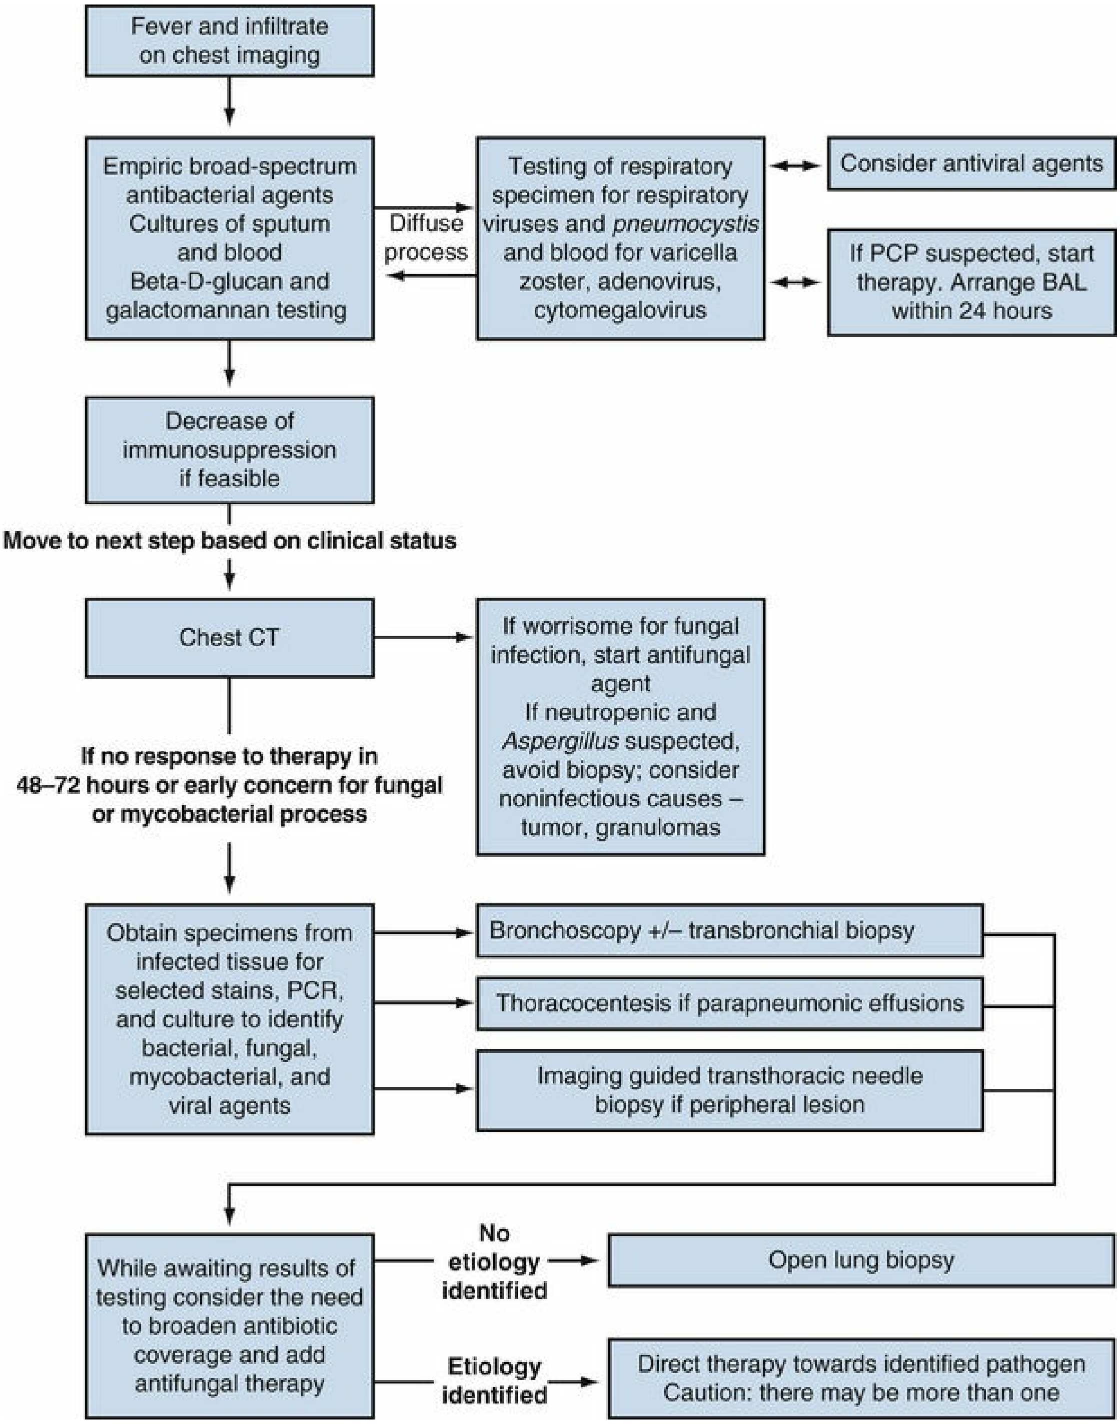
Pathogenesis and Pathologic Findings

The pathogenesis of pneumonia in the immunocompromised host is similar to that of pneumonia in the healthy host, except that defects in host defense play a critical part in the spread of microorganisms from the upper respiratory tract, where they reside as commensals or have recently been acquired from the environment, to the lower respiratory tract and then within the lung itself. Many states of systemic immunodeficiency are accompanied by mucosal immunodeficiency. In the upper respiratory tract, mucosal immunity is primarily mediated by immunoglobulin A (IgA), but in the lower respiratory tract, IgG is more important. There also is a role in the healthy host for mucosal cellular immunity along the respiratory tract (the bronchus-associated lymphoid tissue, or BALT), analogous to Peyer patches along the gastrointestinal tract.[44] Because the function of macrophages, including alveolar macrophages, depends on interleukins secreted by T lymphocytes, the normal phagocytic and microbicidal activities of these important defenders are impaired when cell-mediated immunity is deficient or when critical interleukins are blocked.[14] Clearly, neutrophils also play an important part in the defense of the airway and lung.

Patients with congenital or acquired immunodeficiencies often develop structural abnormalities that compromise the airways, such as ciliary damage and bronchiectasis due to recurrent bronchitis,[37] or intubation in the hospital setting. These defects lead to more rapid and extensive spread of microbes from the upper to the lower respiratory tract. Often, such patients have been exposed to multiple antimicrobial agents and nosocomial organisms, with resultant colonization and subsequent infection by resistant bacteria, yeast, or fungi.

Clinical Diagnosis and Radiographic Manifestations

The diagnosis and management of pneumonia in the compromised host overlap in time. A flow diagram is shown in Fig. 36.1 to serve as a rough guide for decisions.



Fever and infiltrate on chest imaging
Empiric broad-spectrum antibacterial agents Cultures of sputum and blood Beta-D-glucan and galactomannan testing
Diffuse process
Testing of respiratory specimen for respiratory viruses and *pneumocystis* and blood for varicella zoster, adenovirus, cytomegalovirus
Consider antiviral agents
If PCP suspected, start therapy. Arrange BAL within 24 hours
Decrease of immunosuppression if feasible
Move to next step based on clinical status
Chest CT
If worrisome for fungal infection, start antifungal agent If neutropenic and *Aspergillus* suspected, avoid biopsy; consider noninfectious causes – tumor, granulomas
If no response to therapy in 48–72 hours or early concern for fungal or mycobacterial process
Obtain specimens from infected tissue for selected stains, PCR, and culture to identify bacterial, fungal, mycobacterial, and viral agents
Bronchoscopy +/– transbronchial biopsy
Thoracocentesis if parapneumonic effusions
Imaging guided transthoracic needle biopsy if peripheral lesion
While awaiting results of testing consider the need to broaden antibiotic coverage and add antifungal therapy
No etiology identified
Open lung biopsy
Etiology identified
Direct therapy towards identified pathogen Caution: there may be more than one

FIGURE 36.1 Approach to evaluation of the immunocompromised patient with pulmonary infiltrates. The pace of working through the algorithm will depend on the overall clinical status of the patient, prior therapy, and likelihood of finding a pathogen at each step. Invasive procedures are likely to carry higher risk in the neutropenic patient, and therefore a longer trial of empiric therapy and a delay before biopsy may be appropriate for these patients. At any step, if the clinical picture, early tests, or imaging points to a specific etiology, the treatment can be tailored and there may be no need to continue the algorithm. BAL, bronchoalveolar lavage; CT, computed tomography; PCP, *Pneumocystis* pneumonia.

Clinical manifestations of pneumonia in the

immunocompromised host are variable. Fever, with or without cough, may be the only sign of a potentially life-threatening disease.[18] Conversely, a chronic cough without fever also can signal significant lower respiratory tract disease. Certain infections, such as PCP, and interstitial viral pneumonia, caused by RSV, parainfluenza viruses, CMV, or other herpesviruses, impair oxygenation and commonly manifest as hypoxia. Pleuritic chest pain indicates localized pneumonia at the periphery of the lung and, in this setting, can be due to either bacterial or fungal infection.

Radiographic imaging is critical to both the diagnosis and management of pneumonia in immunocompromised children. Conventional radiographs, computed tomography (CT), or both should be performed. Although not generally required, magnetic resonance imaging may be more sensitive than CT for the early recognition of necrotizing pneumonia.[45] High-resolution CT has been shown to have high sensitivity and specificity for the characterization of pneumonia after pediatric hematopoietic stem cell transplantation (HSCT).[46] Among iatrogenically immunocompromised patients, the differential diagnosis often includes noninfectious disorders, such as an underlying malignancy, drug-induced pulmonary disease, emboli, or hemorrhage.[18]

The pattern of abnormality on chest radiograph or CT often is helpful in narrowing the differential diagnosis and guiding further investigations and treatment (Table 36.2). If an interstitial pattern is present, viruses and atypical bacteria such as *Mycoplasma pneumoniae* should be sought by sampling of the nasopharynx and the use of rapid identification methods. A positive test result for respiratory viruses or *M. pneumoniae* in nasopharyngeal specimens may be useful evidence of their causative role in pneumonia; such simple tests can sometimes spare the patient an invasive procedure such as bronchoscopy or lung biopsy. Definitive diagnosis of *P. jirovecii* pneumonia depends on finding “cysts” in pulmonary secretions. In older children, these “cysts” sometimes can be identified in a hypertonic saline–induced sputum sample, but the most useful procedure is bronchoscopy with bronchoalveolar lavage (BAL) or brush biopsy. In the proper clinical setting, however, a positive β-D-glucan test or *P. jirovecii* polymerase chain reaction (PCR) can provide sufficient evidence for the presumptive diagnosis of PCP. Diagnosis of CMV pneumonia often is difficult because CMV can colonize the upper respiratory tract asymptomatically, and its isolation from BAL fluid may not be meaningful. The definitive diagnosis can be made by the presence of characteristic inclusion bodies in biopsy tissue. In the proper clinical setting, identification of CMV in circulating white blood cells by fluorescence testing or at high levels in plasma or serum by PCR suggests CMV as the cause of pneumonia.[47]

TABLE 36.2

Radiographic Patterns and Pathogens of Pneumonias in Immunocompromised Hosts

Radiographic Pattern	Likely Pathogens	Diagnostic Approach
Diffuse, interstitial	Viruses (CMV, RSV, parainfluenza, HSV) *Mycoplasma pneumoniae*[a] *Chlamydia* spp.[a] *Pneumocystis jirovecii*	Rapid viral, mycoplasmal, or chlamydial diagnostic tests on upper airway secretions; β-D-glucan for *Pneumocystis;* bronchoscopy with PCR or immunofluorescence for viruses, and methenamine silver stain for *Pneumocystis*
Focal, consolidative	Pyogenic bacteria (*Streptococcus pneumoniae, Haemophilus influenzae,* others) Nosocomial bacteria *Legionella* spp. (Also consider fungi and mycobacteria)	Blood cultures Gram stain and culture of deep respiratory tract secretions *Legionella* antigen in urine *Cryptococcus* antigen (blood) *Histoplasma* antigen (urine) Galactomannan (blood) Acid-fast smears Bronchoscopy Biopsy
Micronodular	Viruses (adenovirus, VZV, EBV [LIP]) Mycobacteria *Histoplasma, Candida, Cryptococcus* spp.	Rapid viral diagnostic tests on upper respiratory tract secretions Acid-fast smears, cultures of lower respiratory tract secretions *Histoplasma* antigen (urine) *Cryptococcus* antigen (blood)
Nodular	*Aspergillus* spp., other fungi, agents of mucormycosis *Nocardia* spp. EBV lymphoproliferative disease	Galactomannan (blood) *Histoplasma* antigen (urine) *Cryptococcus* antigen (blood) EBV PCR (blood) Bronchoscopy Biopsy (transbronchial, fine-needle, VATS, or open)

[a] Can also cause patchy infiltrate in less compromised individuals.

CMV, cytomegalovirus; EBV, Epstein-Barr virus; HSV, herpes simplex virus; LIP, lymphocytic interstitial pneumonitis; PCR, polymerase chain reaction. RSV, respiratory syncytial virus; VATS, video-assisted thoracoscopic surgery; VZV, varicella-zoster virus.

Determining the cause of consolidative or nodular pneumonia can be difficult. Invasive pulmonary aspergillosis can mimic tuberculosis on chest CT.[48] Blood should be obtained for culture and, in the appropriate setting, quantitative tests for EBV and CMV. A positive test for galactomannan in the blood supports a diagnosis of invasive *Aspergillus* infection.[49] β-D-glucan also is a useful marker for *P. jirovecii* infection but also can be elevated in other pulmonary fungal infections, including *Aspergillus*.[50] Pleural fluid, if present, should be sampled; often it is sterile, however, when patients have been receiving antimicrobial treatment. Bronchoscopy can be helpful, but organisms causing consolidative infiltrates can colonize the upper respiratory tract, and results of culture may be misleading. Gram stain of deep tracheal secretions or BAL fluid often is helpful in indicating density of bacteria in the lower respiratory tract and in guiding therapy. Protected brush BAL has limited sensitivity in detecting pathogens (50% to 80% or less for small lesions), with similar specificity. Bronchoscopy is particularly useful for diagnosis of PCP and CMV pneumonia, although identification does not prove the organism as causing pneumonia (biopsy may be required). A positive microbiologic result in bronchoscopic specimens is useful for the diagnosis of *M. tuberculosis* and fungal infections, including pulmonary aspergillosis when PCR and galactomannan assays can be performed on alveolar lavage fluid. Open lung biopsy or biopsy obtained during video-assisted thoracic surgery often is the definitive diagnostic procedure. Neither bronchoscopy nor surgical intervention is an attractive option in the setting of severe thrombocytopenia or respiratory failure with hypoxia. For the intubated patient, blind endotracheal suctioning can be useful, especially if quantitative cultures are performed, but with reduced sensitivity and specificity compared with bronchoscopy for focal pneumonias.

There also is a role for empiric antimicrobial treatment for pneumonia in the immunocompromised patient, particularly if the immunocompromised state is likely to be temporary. However, an aggressive approach to definitive microbiologic diagnosis of pneumonia in highly immunocompromised patients often is indicated because appropriate therapy may be complex, prolonged, and toxic, as well as lifesaving.[51]

Management and Therapy

Empiric treatment should be guided by the risks posed by the type of immunocompromise and the radiologic, clinical, and epidemiologic circumstances. The presence of diffuse pulmonary infiltrates, particularly with hypoxia, should generally prompt early investigation for respiratory viruses and consideration for bronchoscopy to identify *P. jirovecii.* Empiric therapy should include trimethoprim-sulfamethoxazole for PCP because infection is potentially life-threatening. In addition, macrolide therapy for *Mycoplasma* or *Legionella* spp. should be considered. Treatment of CMV pneumonia with ganciclovir or Foscarnet, as well as changes in transplantation practices, have been associated with increased survival after HSCT.[52] Although it is clearly preferable to perform diagnostic tests *before* therapy has been started, *P. jirovecii* usually can be identified for several days after treatment has been started.[53] Decision concerning adjunctive corticosteroid therapy for treatment *of P. jirovecii* pneumonia, however, should generally await definitive diagnosis.

Localized infiltrates are more likely due to bacterial infection, and empiric antibiotic therapy should include agents that are effective against resident flora and nosocomial organisms, including methicillin-resistant *S. aureus*. Nodular infiltrates can suggest fungal infection[35] or, especially if associated with lymphadenopathy, lymphoproliferative disease.

Patients with prolonged neutropenia who fail to improve despite treatment with broad-spectrum antibacterial agents will need extensive diagnostic testing and empiric treatment for *Aspergillus* infection. Voriconazole is the recommended primary therapy for most patients with pulmonary aspergillosis, although liposomal amphotericin B also can be used along with reversal of underlying immune defects. No “rule,” however, is completely reliable, and further clinical and epidemiologic information always should be used to guide decisions. Aggressive diagnostic procedures are indicated more urgently if the illness is severe and the immunosuppressed state is likely to be of longer duration.

Some clinicians serially monitor the biomarkers used to diagnose infections (e.g., quantitative PCR, galactomannan, β-D-glucan) to evaluate response to therapy. Few data exist, however, to guide interpretation or determine the utility of these tests measured serially in managing pulmonary infections.[54]

Colony growth factors can be used to decrease the period of neutropenia among neutropenic patients. Their use, however, has not been demonstrated to be of benefit for the management of pneumonia or other established infections, and there are case reports of pulmonary deterioration among healthy stem cell donors and patients with growth factor–induced neutropenia recovery.[55] There is little published information regarding the use of inhaled antimicrobial agents for the management of respiratory tract pathogens in the immunocompromised host.

Prevention

Preventive strategies depend on the nature of the immunodeficiency, the consequent anticipated threats, and the circumstances under which these threats occur (after organ transplantation, during chemotherapy, or in an evolving immunodeficiency, such as with HIV infection). All preventive modes are important. Pathogens should be avoided whenever possible. Examples of such simple preventive measures are the use of barrier precautions in the hospital environment, influenza immunization of family contacts, avoidance of *Salmonella*-contaminated foods or reptiles at home, and, most important, maintenance of good hand hygiene by family caregivers, medical personnel, and patients. Vaccines should be administered in such a way as to optimize response (e.g., *before* solid-organ transplantation, or early in the life of an infant with HIV infection, when $CD4^+$ lymphocyte counts are likely to be highest). When particular vaccines are contraindicated (e.g., live viral vaccines immediately after stem cell transplantation), ineffective (as in children with many congenital immunodeficiencies), or not available, the use of pooled immune globulin, pathogen-specific immune globulin (such as CMV immune globulin), or monoclonal antibody (such as palivizumab to prevent severe disease due to RSV) can be protective. In selected circumstances, antimicrobial chemoprophylaxis is extremely effective in preventing important and potentially life-threatening pneumonias, such as those due to *P. jirovecii,* HSV, and CMV. In certain diseases, such as chronic granulomatous disease, interferon γ, injected 3 times per week, reduces the occurence of serious infections by as much as two thirds.[56] Recommendations for prevention of infection by specific organisms such as *P. jirovecii*, CMV, and *Aspergillus* depend on clinical circumstances, which are detailed in other chapters.

Endocarditis and Other Intravascular Infections

Stéphanie Levasseur, Lisa Saiman

The American Heart Association (AHA) and the European Society of Cardiology, as well as other national societies, provide updated scientific statements on many of the topics discussed in this chapter.[1–9] Readers are encouraged to review these consensus statements and seek updated documents by these authoritative groups.

Infective Endocarditis

Infective endocarditis is an uncommon infection of the cardiac endothelium. In this disease process, pathogens become enmeshed in fibrin and platelets to form *vegetations,* which are attached to heart valves, mural endocardial surfaces, or the endocardium that forms over prosthetic material such as prosthetic valves, pacemaker leads, or catheters. The historical risk factors of rheumatic heart disease and unrepaired congenital heart disease remain relevant, particularly in developing countries,[10–12] but in developed countries, endocarditis in children and young adults occurs more often after surgery for congenital heart disease, as a result of complications of intravenous drug abuse or use of indwelling central venous catheters, or as healthcare-associated infections (see Chapter 100).[12–20]

Endocarditis was uniformly fatal in the preantibiotic era, but the rate of cure in referral centers is as high as 90% with appropriate treatment.[12,21–25] Mortality rates of 3.5% to 6.8% were reported in two studies from the United States using administrative datasets of children hospitalized with endocarditis.[26,27] However, the crude mortality rate of endocarditis when including endocarditis diagnosed postmortem may be as high as 21% to 24%.[22,28]

Etiologic Agents and Associated Risk Factors

The pathogens causing endocarditis in children from representative case series are shown in Table 37.1. Streptococci, especially viridans streptococci (e.g., *Streptococcus sanguis, S. mitis, S. salivarius, S. mutans,* and *S. oralis*) are frequent causes of endocarditis. These pathogens generally are associated with infection after rheumatic fever and unrepaired congenital heart disease and with late postoperative endocarditis.[29–31] Staphylococci are more common than streptococci in some series.[21,27,32] Coagulase-negative staphylococci (CoNS) can cause endocarditis after cardiac surgery, and *S. aureus,* including community-acquired methicillin-resistant *S. aureus* (CA-MRSA), causes endocarditis in normal hearts as well.[33] *Candida* and *Aspergillus* spp. increasingly are common causes of healthcare-associated endocarditis, particularly among patients in the neonatal intensive care unit (NICU), with central venous catheters, or after prosthetic valve surgery.[31,34,35] Gram-negative bacilli and fastidious gram-negative oropharyngeal flora, the so-called HACEK organisms, an acronym for ***H**aemophilus* spp., ***A**ggregatibacter* spp., ***C**ardiobacterium hominis;* ***E**ikenella corrodens;* and ***K**ingella kingae,* are uncommon causes of endocarditis in children. Among the HACEK group, *K. kingae* and *A. parainfluenzae* are the most common causes of endocarditis in children.[36] In the preantibiotic era, *Streptococcus pneumoniae* caused 15% of cases of endocarditis. Today, pneumococcal endocarditis is rare but is associated with a high rate of mortality.[37]

TABLE 37.1

Trends in Agents of Infective Endocarditis

Period of Data Collection	**1950–1992**[23,28,50,191,192]	**1990–2008**[164,169,193-195]
Number of cases	421	202
Streptococci		
Viridans streptococci	158 (38%)	58 (29%)
Streptococcus pneumoniae	11 (3%)	3 (1%)
Group B streptococci	3 (<1%)	1 (<1%)
Other	2 (<1%)	1 (<1%)
Enterococci	16 (4%)	20 (10%)
Staphylococci		
Staphylococcus aureus	113 (27%)	46 (23%)
Coagulase-negative staphylococci	22 (5%)	25 (12%)
Gram-negative bacilli	26 (6%)	19 (9%)
Fungi	9 (2%)	17 (8%)
Other organisms	5 (1%)	—
Polymicrobial	4 (1%)	12 (6%)
Culture negative	58 (14%)	21 (10%)

Culture-negative endocarditis seems to be less common in children than in adults. Approximately 5% to 10% of children with endocarditis have sterile blood cultures. Previous treatment with antibiotics is a common cause of negative blood cultures, but fastidious HACEK organisms and other rare fastidious pathogens such as *Bartonella, Brucella, Mycoplasma, Legionella,* and *Coxiella burnetii* can be causative. Non-HACEK pathogens are better detected by serologic or polymerase chain reaction (PCR) testing.[38–42] Endocarditis in children is rarely caused by mycobacteria, *Chlamydia psittaci,*[43] and *Tropheryma whipplei.*[43]

Epidemiology

The true incidence of endocarditis in children has been difficult to ascertain because the literature primarily derives data from referral centers. Between 1930 and 1972, 1 per 2000 to 5000 pediatric hospital admissions were due to endocarditis, and during the 1960s to 1980s, incidence was 1 per 500 to 1000 hospitalizations.[44–46] In 2003, 1 in 3500 randomly selected hospital admissions from a national database were attributed to endocarditis,[27] whereas a multicenter study conducted from 2003 to 2010 reported that endocarditis was associated with 0.05 to 0.12 per 1000 pediatric hospital admissions.[47] On the other hand, the risk of endocarditis between birth and the age of 18 years was found to be 6.1 per 1000 children with congenital heart disease (or 4.1 cases in 10,000 person-years) in a recent population-based cohort from Canada.[48] In a cohort of adults with congenital heart disease from the Netherlands, the incidence was significantly higher at 11 cases in 10,000 person-years.[49]

The risk factors for endocarditis in children have changed over the past several decades. As shown in Table 37.2, congenital heart disease is the most common predisposing condition in the US. Although surgical correction of ventricular septal defect or patent ductus arteriosus substantially reduces the risk for endocarditis, other interventions such as palliative shunts, valve replacement, and placement of pacemakers or defibrillators, or both, can increase the risk for endocarditis due to the sustained presence of foreign material in the bloodstream.[50] Advances in surgical techniques and supportive care now permit earlier repairs of certain lesions (e.g., tetralogy of Fallot) as well as neonatal palliation of previously inoperable lesions.[51,52] These changes are associated with increased endocarditis, including early postoperative endocarditis, occurring in younger patients, with a median age of ≤2 years in some series.[26,28,32,48] However, endocarditis can occur years after repair of congenital heart defects. Of note, 18% to 39% of patients with endocarditis in developed countries have no previously known cardiac defect.[12,20,21,23–26,28,32]

TABLE 37.2

Trends in Underlying Cardiac Diseases in Children With Infective Endocarditis

Reference	**Series 1**[45]	**Series 2**[21]	**Series 3**[28]	**Series 4**[26]
Years of study	1930–1972	1977–1992	1992–2004	2004-2010
Number reported	266	62	85	1033
Cardiac defect, *n* (%)				663 (64%)
Congenital cardiac defect, *n* (%)	208 (78%)	40 (64%)	68 (80%)	NA
Acyanotic, *n* (%)	NA	18 (45%)	48 (71%)	517 (78%)
Cyanotic, *n*	NA	22	20	146
Rheumatic heart disease	37 (14%)	3 (5%)	1 (1%)	NA
No cardiac defect	21 (8%)	19 (31%)	13 (18%)	370 (36%)

NA, not available.

Neonatal endocarditis is not rare and usually arises as a complication of extreme prematurity, major surgery, or prolonged use of indwelling central venous catheters (CVCs).[29,31,44,53,54] Fewer than 30% of neonates with endocarditis have congenital heart disease, and most endocarditis is right sided.[32,55] Older children without cardiac defects also can develop right-sided endocarditis, including adolescents with intravenous drug abuse, those with pacemakers, or critically ill patients with CVCs.[27,28,44,56–64]

A significant increase in the hospitalization rates for endocarditis in the American adult population was noted from 2000 to 2011 with an increase of 11 to 15 per 100,000 population.[65] The proposed explanations include an aging population, increases in individuals with high-risk conditions such as diabetes and those requiring hemodialysis, and increased survival of adults with congenital heart disease and prosthetic implants.

Pathogenesis and Pathologic Findings

Native Valve Endocarditis

The most important factor in the pathogenesis of endocarditis is disruption of the endothelium, typically caused by turbulent blood flow or foreign body (e.g., a CVC) in contact with the endocardium, or both. Turbulence generally is from an area of high pressure to an area of low pressure, that is, across a ventricular septal defect or regurgitation through an incompetent valve.[18,29,46,53,66,67] Erosion of endothelium occurs, facilitating deposition of platelet-fibrin thrombi on the mural surface or on an abnormal valve on the down-pressure side.

Important pathogen factors include bacteremia or bloodstream infection (BSI) or fungemia and microbial adhesins. The peptidoglycan surface of oral streptococci facilitates adherence to endothelial cells. Similarly *S. aureus* binds to collagen, fibronectin, laminin, vitronectin, and fibrinogen.[1,68] Microbial surface components that recognize adhesive matrix molecules (MSCRAMMS) likely are virulence factors of *S. aureus.*[15] Patients with *S. aureus* endocarditis have higher serum levels of adhesin molecules than patients with *S. aureus* BSI without endocarditis.[69] The bacterial adhesins of CoNS are less well understood but may be capsular polysaccharides.[70]

The rate of bacteremia associated with common events and medical procedures is shown in Table 37.3.[71] Although dental procedures, such as drainage of an abscess, gingival surgery, and tooth extraction, are particularly likely to cause bacteremia, transient bacteremia after common daily activities such as tooth brushing is far more frequent. Thus an antecedent event clearly responsible for endocarditis rarely is identified.[2]

TABLE 37.3

Rate of Bacteremia After Various Procedures

	Episodes of Bacteremia per Episode[71]	
Procedure	**Mean (%)**	**Range (%)**
Tooth extraction	60	18–85
Periodontal surgery	88	60–90
Tonsillectomy	35	33–38
Rigid bronchoscopy	15	
Tracheal intubation	<10	0–16
Urinary tract catheter insertion or removal	13	0–26
Upper endoscopy	4	0–8
Barium enema	10	5–11
Colonoscopy	5	0–5
Cardiac catheterization	2	0–5

Right-sided endocarditis can be due to a CVC extending into the structurally normal heart. In an experimental model in rabbits, endocarditis only develops when bacteremia is preceded by placement of an intravenous polyethylene catheter across the tricuspid valve into the right ventricle.[59] The catheter acts as a foreign body, abrading endocardial and valvular surfaces and resulting in sterile vegetations that serve as a nidus for infection.

Postoperative Endocarditis

The pathogenesis of endocarditis occurring ≤6 months (early) and >6 months after surgery (late) differ. In the early postoperative period, denuded endothelium and exposed sutures are adjacent to prosthetic material; thrombi can form at these sites with fibrin deposition. Endocarditis can result if bacteremia or fungemia follows contamination of intravenous solutions, the cardiac bypass pump, a surgical site, CVC, or exposed pacemaker wires or intracardiac catheters. In addition, bacterial or fungal contamination of the operative site can be caused by infected homografts or the colonized hands of healthcare personnel.[72–74] Late postoperative endocarditis occurs after re-endothelialization of cardiac and vascular surfaces, with pathophysiology more akin to native valve endocarditis.

Pacemaker and Ventricular Assist Device Infections

Placement of a pacemaker or cardioverter-defibrillator in children and adolescents is increasing.[75,76] Contamination during placement and infection of the pulse-generator pocket are the usual preceding events. Endocarditis is relatively rare and accounts for approximately 10% of implantable device-associated infections,[3] although younger patients may have more frequent lead-wire infections than older patients.[76,77] Complete removal of the device is recommended when a deep pocket infection occurs because of the high risk for relapse and for contaminating the intravascular portion of the device.[57,78]

Ventricular assist devices (VADs) are increasingly being used to support patients awaiting heart transplantation.[79] Although data are limited, the rate of infectious complications is high, occurring in 18% to 59% of patients, and complications include surgical site infections, BSIs, and endocarditis presenting as relapsing BSI.[80–82] Management of VAD-related infections is highly complex owing to the critical need for the device, presence of intravascular and intracardiac foreign material, and high risk for relapse.

Pathologic Lesions

Gross Findings.

Vegetations can be single or multiple and vary in size from 1 to 2 mm to several centimeters (Figs. 37.1 and 37.2).[1] Endocarditis can destroy the underlying valve or perforate valve leaflets; rupture the chordae tendineae, papillary muscle, or interventricular septum; or lead to abscess of the valve ring. Healing can result in fibrosis and calcification. Myocardial abscesses and pericarditis also can be present.

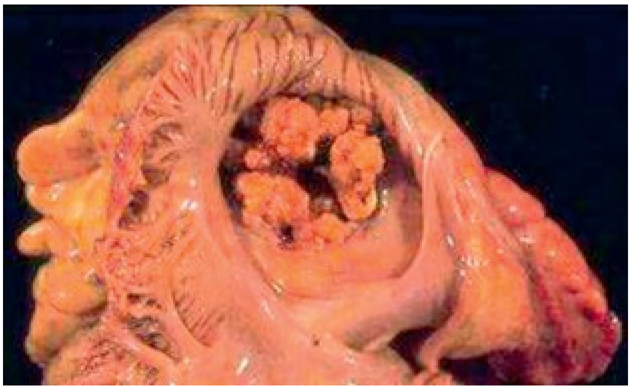

FIGURE 37.1 Infective endocarditis of the surface of the mitral valve. Note the healing masses at 10:00 and 2:00; this is "subacute" endocarditis with healing granulation tissue and fibrosis microscopically. No exophytic acute vegetation is present. (Courtesy of Charles Marboe, MD, Department of Pathology, Columbia University.)

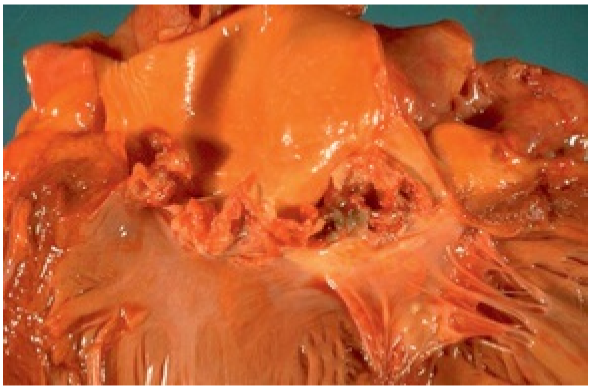

FIGURE 37.2 Infective endocarditis of the aortic valve. The left ventricular outflow tract is below the severely damaged valve, and the aorta is above. The anterior leaflet of the mitral valve is to the right and below the aortic valve. The aortic valve leaflets are almost entirely destroyed by the multiple vegetations of acute endocarditis. (Courtesy of Charles Marboe, MD, Department of Pathology, Columbia University.)

Microscopic Findings.

Vegetations consist of fibrin, platelets, and bacteria. Neutrophils and red blood cells also can be seen (Fig. 37.3).

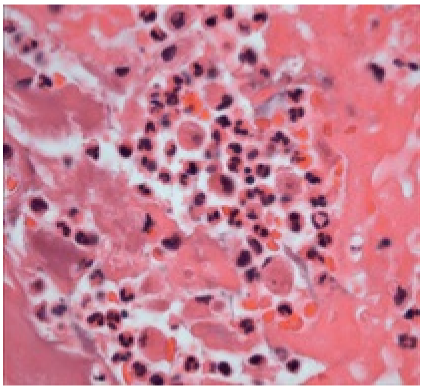

FIGURE 37.3 The histopathology of infective endocarditis. Vegetations are composed of neutrophils, macrophages and fibrin (*red*). Organisms are present in acute, untreated endocarditis. (Courtesy of Charles Marboe, MD, Department of Pathology, Columbia University.)

Embolic Findings.

Pathologic processes after emboli to distal organs consist of abscesses or infarction, or both. In the kidney, the lesions of glomerulonephritis also can occur, characterized by subepithelial deposits containing immunoglobulin G (IgG), IgM, IgA, or complement. Mycotic aneurysms are detected most commonly in the central nervous system and arise from direct bacterial invasion, embolic occlusion, or immune complex deposition within the arterial wall. Intracerebral or subarachnoid hemorrhage can result from emboli. Emboli to the lung can result in pneumonia, lung abscess, empyema, or effusion.

Clinical Manifestations

Symptoms

Classically, the clinical presentations of endocarditis were categorized as either subacute, generally manifesting with a prodrome of moderate illness and nonspecific symptoms for several weeks, or acute, with a short prodrome and a sepsis-like presentation. However, individual cases can have mixed features, and the presentation does not always predict the infecting microorganism.

Common symptoms of endocarditis in children are shown in Table 37.4. The subtle and nonspecific nature of symptoms can delay diagnosis for weeks.[29,53,83,84] Endocarditis should be suspected in patients with (1) congenital heart disease or other risk factors for endocarditis with unexplained fever and fatigue (or anemia) that can remit temporarily when oral antibiotics are prescribed; (2) congenital heart disease with new onset of congestive heart failure or conduction abnormalities, especially if accompanied by fever; (3) abrupt onset of septicemia or appearance of vascular lesions in soft tissues or mucous membranes; and (4) structurally normal hearts in whom CVC has been removed but blood cultures are persistently positive.

TABLE 37.4

Frequency of Findings in Pediatric Infective Endocarditis

Symptom	**Frequency (%)**[21,30,46,53,66,83,164]
Fever	75–100
Malaise	50–75
Anorexia/weight loss	25–50
Heart failure	25–50
Arthralgia	17–50
Chest pain	0–25
Neurologic symptoms (focal neurologic deficit, aseptic meningitis)	0–25
Gastrointestinal symptoms	0–50
Sign	**Frequency (%)**[21,30,46,52,64,81,162]
Fever	75–100
Splenomegaly	50–75
Petechiae	21–50
Embolic phenomenon	25–50
New or changed murmur	21–50
Clubbing	0–10
Osler nodes	0–10
Roth spots	0–10
Janeway lesions	0–10
Splinter hemorrhages	0–10
Conjunctival hemorrhages	0–10
Abnormal Laboratory Finding	**Frequency (%)**[a]
Positive blood culture	75–100
Elevated erythrocyte sedimentation rate	75–100
Anemia	75–90
Presence of rheumatoid factor	25–50
Hematuria	25–50
Low serum complement	5–40

[a] From references 21, 30, 46, 52, 64, 81, 162.

Vegetations, especially those on valve leaflets, can break off into the circulation. Significant morbidity can result from infectious emboli to the lungs (right-sided endocarditis) or to the central nervous system, kidney, spleen and extremities (left-sided endocarditis). Embolic events can be the predominant clinical feature in some patients.[85,86] Thus patients with fever and neurologic symptoms or with pneumonia or pulmonary emboli should be promptly evaluated for endocarditis.

Physical Examination

Table 37.4 shows frequency of physical findings in endocarditis.[4] Subtle changes in an existing murmur or detection of a new murmur in a febrile and tachycardic child may be difficult to appreciate. In patients with rapidly progressing infection, physical examination may not reveal the usual signs of endocarditis, and thus endocarditis is suspected because of underlying heart disease or persistently positive blood cultures or embolic events, including splinter hemorrhages (i.e., dark linear streaks in the nail beds). Signs due to deposition of immune complexes composed of bacterial antigens, antibodies, and complement are rare in children.[1] These include Osler nodes, that is, small (2–15 mm), painful, purplish lesions in the pulp of the fingers or toes that persist for hours or days; Janeway lesions, that is, painless hemorrhagic macular plaques on the palms or soles due to emboli that persist for days; or Roth spots, that is, small hemorrhagic retinal lesions with a pale center, usually near the optic disk.

Differential Diagnosis

When the onset of endocarditis is abrupt, the differential diagnosis includes septicemia, septic shock, and other acute cardiac inflammatory diseases, such as myocarditis, pericarditis, or rheumatic fever. Persistently positive BSI can arise from suppurative thrombophlebitis, as described later. If the onset of endocarditis is insidious, with prolonged or intermittent fever, the differential diagnosis includes fever of unknown origin, prolonged viral illness, and collagen vascular disorders. In patients with systemic lupus erythematosus or the antiphospholipid syndrome, sterile, verrucous vegetations called Libman-Sacks vegetations can be misdiagnosed as infective endocarditis.[87] Other echocardiographic findings that can mimic infective endocarditis include ruptured chordae and flail leaflet, severe myxomatous valvular changes, rheumatic fever valvular damage, and some cardiac tumors.

If the complications of endocarditis are the main clinical presentation, the differential diagnosis includes stroke, vasculitis, or cerebral vascular malformation. Glomerulonephritis can be the predominant presenting sign and endocarditis must be distinguished from other causes.[88,89]

Laboratory Findings and Diagnosis

Ancillary Laboratory Tests

Supporting laboratory test results are presented in Table 37.4. However, with the exception of positive blood cultures, these tests are nonspecific and are not diagnostic. In contrast, immunologic phenomena, including presence of rheumatoid factor, hematuria, nephritis, and low serum complement associated with glomerulonephritis, are considered minor diagnostic criteria.[90] Laboratory evidence of cardiac injury, that is, elevated serum levels of troponin I and B-type natriuretic peptide, is associated with worse outcomes in adults and may play a role in identifying patients who would benefit from surgical intervention.[91,92]

Microbiologic Evaluation

Persistent bacteremia or fungemia is the most helpful laboratory test in endocarditis. In streptococcal endocarditis, 96% and 98% of the first versus second blood cultures were found to be positive.[93] In endocarditis caused by other species, 82% to 94% and 100% of the first versus second blood cultures yielded the diagnosis.[94] Total volume of blood sampled is most important. Nevertheless, collection of 3 to 5 specimens from separate venipuncture sites is recommended to optimize recovery of a pathogen, particularly a fastidious microorganism, and to clarify a possible contaminated culture. Determining the clinical significance of a single positive blood culture, particularly with a possible contaminant (e.g., CoNS or occasionally viridans streptococci) can be difficult. If recent antibiotics have been received and the patient is clinically stable, antimicrobial therapy should be suspended for 24 hours to improve the yield of blood cultures. Ideally, each anaerobic and aerobic bottle is inoculated with 1 to 3 mL of blood for infants, 3 to 5 mL for small children, and 5 mL for larger children to optimize detection of pathogens, particularly in the setting of low-level bacteremia.[95] If limited blood is available for culture, the aerobic bottle should be inoculated.

The clinical microbiology laboratory should be alerted that endocarditis is being considered. Modern blood culture technologies can detect nutritionally variant streptococci and the HACEK organisms. Prolonged incubation or specialized media rarely are required. Additional testing sometimes is required (Table 37.5) and can include serologic tests, urine antigen tests, and molecular technologies, that is, PCR testing for 16S ribosomal DNA (rDNA) performed on excised valves and serum specimens (e.g., *Bartonella*) cases.[1,41,96] With the exception of *C. burnetii* antibodies, these diagnostic assays are performed only at specialized laboratories, are not standardized, and hence are not yet diagnostic criteria in the modified Duke classification.[1,97]

TABLE 37.5

Adjuvant Diagnostic Testing for Culture-Negative Endocarditis[41,42]

Pathogen	Test	Comment
Aspergillus spp.	Serology	Indirect hemagglutination assay
Bartonella henselae, Bartonella quintana	Blood culture Valve culture Serology PCR	Direct inoculation of blood agar, 5% CO_2 and shell vial Indirect immunofluorescent antibody test; titer ≥1:800 Western immunoblot
Brucella melitensis	Serology	IgG ≥1:200[a]
Coxiella burnetii	Blood/valve culture Serology PCR	Routine or heparinized blood inoculated in shell vials to detect bacteria by immunofluorescence[a]
		Anti–phase I IgG antibody titer >1:800 is major criterion
		IgG, IgA, IgM to phase I and phase II[a]
		htpAB-associated repetitive element of *C. burnetii*[a]
Legionella pneumophila	Serology	Indirect immunofluorescent antibodies ≥1:256
	Urine antigen	Available for serogroup 1
Mycoplasma pneumoniae	Serology PCR	IgG ≥1:200[a]
Tropheryma whipplei	See below	Etiologic agent of Whipple disease
Unknown	16S rDNA blood	Universal primer to identify bacteria by amplification and sequencing[a]
	16S rRNA valve	Universal primer for yeast
	18S rDNA blood	

	18S rRNA valve	
	Pathology of valve	Immunoenzymatic assay with polyclonal specific antibodies for *Coxiella, Bartonella, Chlamydia, Tropheryma*[a]

[a]Available in reference laboratories.

Ig, immunoglobulin; PCR, polymerase chain reaction.

Diagnostic Imaging

Echocardiography is the main diagnostic imaging modality to identify the pathology and define the cardiac complications of endocarditis and must be performed early to ensure rapid diagnosis and appropriate treatment, including surgical intervention if indicated.[98,99] Two-dimensional imaging can visualize vegetations as small as 2 mm, intracardiac abscesses, pseudoaneurysms, valve aneurysms, and dehiscence of a prosthetic valve (Fig. 37.4). Color and spectral Doppler imaging can identify flow through cardiac structures, as well as flow in pseudoaneurysms, fistulas, and valve dehiscences, and can identify consequences of pathologic lesions, including valvar insufficiency and perforations. Echocardiography can be falsely negative early in disease because of small vegetations or embolization and should be repeated within 7 to 10 days if there is continuing suspicion for endocarditis.[1,5,100] Echocardiograms remain negative in about 15% of infective endocarditis cases; thus a negative study does not rule out endocarditis.[99]

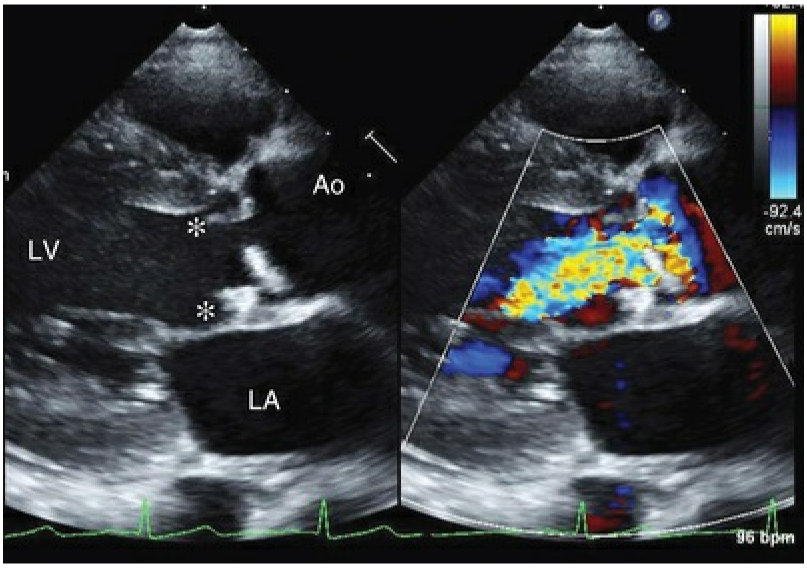

FIGURE 37.4 Valvular vegetations (*asterisk*) and their destructive effect on a bicuspid aortic valve. The color

Doppler image demonstrates severe valvular regurgitation from lack of valve coaptation. Ao, aorta; LA, left atrium, LV, left ventricle.

In adult populations, transthoracic echocardiography (TTE) has significantly lower sensitivity (40% to 63%) compared with transesophageal echocardiography (TEE) (≥90%).[101–105] TEE is used less frequently in pediatrics because of its relative invasiveness, its technical limitations in very small children, and the higher sensitivity of TTE (≥80%).[1,106–111] TEE does have a role in pediatrics to evaluate prosthetic valves, to assess certain complications, particularly aortic root abscesses, and to evaluate patients with complex anatomy from previous cardiac surgery, thoracic cage abnormalities, or weight >60 kg.[4,9,111] Intraoperatively, TEE is invaluable to improve visualization of lesions and to assess surgical results.

Echocardiography plays a central role during the treatment of endocarditis, establishing the need for urgent or emergent surgery in cases of heart failure (e.g., acute severe valvar regurgitation or obstruction) and uncontrolled infection (e.g., abscess, fistula).[98,112] Serial echocardiograms are used to monitor hemodynamic consequences of endocarditis and enlarging vegetations and to detect later complications (e.g., perivalvular extension and abscesses) that may require surgery. Echocardiography can be used to assess heightened risk for important embolization, by vegetation size (>10 mm), location (mitral valve anterior leaflet), and increased mobility of the vegetation. In certain cases of early embolism, urgent surgery may be indicated.[85,98,113,114]

In adult populations, three-dimensional echocardiography improves characterization of the pathology associated with endocarditis although concerns remain regarding inferior resolution for fast moving structures.[1,115–119] Cardiac magnetic resonance imaging (MRI) and computed tomography (CT) offer adjunctive imaging strategies.[120–124] CT may optimally visualize abscess extension (Fig. 37.5) and pseudoaneurysms,[120,121] and MRI may be most useful to investigate extracardiac complications including cerebral and splenic embolic infarcts.[99] Positron emission tomography (PET) with ^{18}F-fluorodeoxyglucose combines nuclear and CT technologies and is a promising imaging modality that detects inflammatory leukocytes.[125–129] Reduction in radiation exposure will be necessary before PET is used commonly in children. Finally, intracardiac echocardiography has been found to increase diagnostic yield compared with TEE among adults being evaluated for right-sided vegetations associated with leads of implantable cardiac devices.[130]

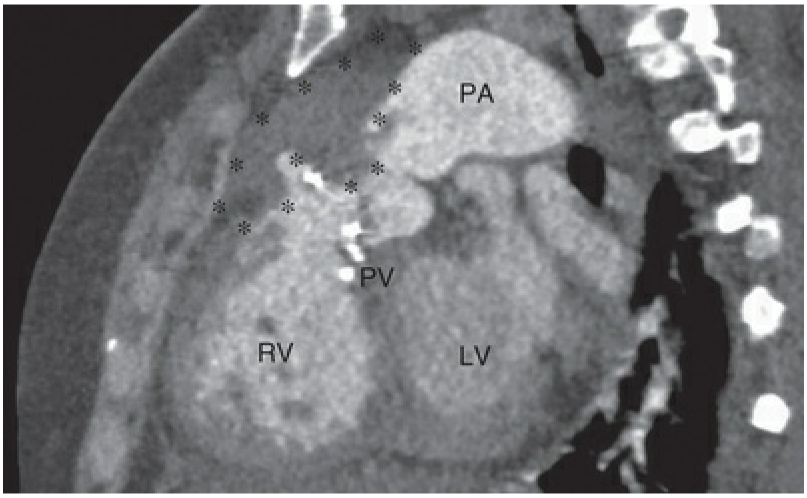

FIGURE 37.5 Computed tomographic sagittal view of the right ventricular outflow tract in a patient with tetralogy of Fallot who had previously undergone pulmonary valve replacement and who presented with prosthetic pulmonary valve endocarditis. Note the extension of abscess anteriorly (*asterisks*) presumably from fistula formation. RV, right ventricle; LV, left ventricle; PA, pulmonary artery; PV, pulmonary valve.

Diagnostic Criteria

The diagnosis of endocarditis is obvious in the setting of new valvular vegetations and multiple positive blood cultures. Diagnosis can be challenging in high-risk patients with negative blood cultures or echocardiograms, or with blood cultures positive for unusual pathogens. Diagnostic criteria originally were developed as epidemiologic and research tools, but after years of revisions, criteria have an important clinical role in more complex cases.[131] The modified Duke Criteria (Boxes 37.1 and 37.2)[97] now are accepted widely as a guide for diagnosing endocarditis[1,98] and can be used in children.[4,132–134] However, diagnostic criteria cannot replace clinical judgment. Treating patients who do not meet criteria fully may still be indicated. It is likely that further modifications of the Duke Criteria will be made as improvements in microbiologic and imaging tests become validated and available more readily.[1]

Box 37.1

Modified Duke Clinical Criteria for Diagnosis of Infective Endocarditis[a]

Definite Infective Endocarditis

Pathologic Criteria

- Microorganisms demonstrated by culture or histology in a vegetation, embolized vegetation, or intracardiac abscess
- Pathologic lesions (vegetation or intracardiac abscess) with active endocarditis confirmed by histology

Clinical Criteria

- 2 major criteria
- 1 major and 3 minor criteria
- 5 minor criteria

Possible Infective Endocarditis

- 1 major criterion and 1 minor criterion
- 3 minor criteria

Rejected

- Firm alternative diagnosis for manifestations of endocarditis
- Resolution of endocarditis manifestations with antibiotic therapy ≤4 days
- No pathologic evidence of infective endocarditis at surgery or autopsy with antibiotic therapy for ≤4 days

- Does not fulfill criteria above

---

[a] Any one of the findings listed above is taken as evidence.

Modified from Li JS, Sexton DJ, Mick N, et al. Proposed modifications to the Duke criteria for the diagnosis of infective endocarditis. Clin Infect Dis 2000;30:633–638.

Box 37.2

Definitions of Major and Minor Criteria Used in the Duke Schema for the Diagnosis of Infective Endocarditis

Major Criteria

1. **Positive blood culture for IE**

- Typical microorganism consistent with IE from two separate blood cultures:
  - Viridans streptococci[a]
  - *Streptococcus gallolyticus bovis*
  - HACEK group (see group)
  - *Staphylococcus aureus*
  - Community-acquired enterococci (without a primary focus)
- Microorganism consistent with IE from persistently positive blood cultures if:
  - At least 2 positive blood cultures sampled more than

12 hours apart

- All 3 or a majority of more than 4 blood cultures

- Single positive blood culture for *Coxiella burnetii* or IgG antibody titer >1:800

2. **Evidence of endocardial involvement by positive echocardiogram for IE, defined as:**

- Oscillating intracardiac mass on valve or supporting structures, in the path of regurgitant jets, or on implanted material

- Abscess

- New partial dehiscence of prosthetic valve

- New valvular regurgitation (worsening or changing of preexisting murmur not sufficient)

Minor Criteria

1. **Predisposing heart condition or intravenous drug abuse**

2. **Fever: temperature ≥38°C**

3. **Vascular phenomena:** major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhages, Janeway lesions

4. **Immunologic phenomena:** glomerulonephritis, Osler nodes, Roth spots, rheumatoid factor

5. **Microbiologic evidence:** positive blood culture but does not meet major criteria or serologic evidence of active infection with organism consistent with IE

IE, infective endocarditis; IgG, immunoglobulin G.

---

[a] Includes nutritionally variant strains (*Abiotrophia* spp).

Modified from Li JS, Sexton DJ, Mick N, et al. Proposed modifications to the Duke criteria for the diagnosis of infective endocarditis. Clin Infect Dis 2000;30:633–638.

Management

When endocarditis is suspected, urgent evaluation of hemodynamic status is critical. If signs and symptoms of heart failure are present, an echocardiogram and several blood cultures are obtained quickly, and empiric antibiotic therapy and hemodynamic support are provided without delay. Patients with heart failure often require urgent cardiac surgery, which can be lifesaving.

Empiric Antibiotic Therapy

Presumptive antibiotic therapy is based on patient age, clinical presentation, comorbid conditions, preexisting cardiac status, recent cardiac surgery, prior episodes of BSI or endocarditis, community versus healthcare acquisition, and local antibiogram. Antimicrobial treatment for endocarditis in children is derived from recommendations developed for adults; pediatric infectious disease consultants should help select an empiric antibiotic regimen (Tables 37.6 and 37.7). High doses of bactericidal antibiotics delivered intravenously are needed; penetration of bioactive cells and substances into the infected vegetation can be difficult. Bacteriostatic agents are less effective. Pathogens exist within a biofilm and are not metabolically active, rendering them less susceptible to β-lactam and other cell-wall active agents. Furthermore, heart valves do not have a dedicated blood supply. When combination therapy—generally a β-lactam agent plus an aminoglycoside—is used for synergy, close temporal administration of the two drugs may maximize potential activity.[1]

TABLE 37.6

Antimicrobial Agents for Treatment of Pediatric Infective Endocarditis Caused by Gram-Positive Cocci

Definitive Therapy	Agent	Prosthetic Material or Artificial Valves	
		Duration, if Absent	Duration, if Present
STREPTOCOCCI AND RELATED SPECIES			
(Includes most viridans streptococci and *Streptococcus gallolyticus* [formerly *S. bovis*])			
Highly susceptible to penicillin (MIC ≤0.12 μg/mL)	Penicillin G (or ampicillin) *or*	4 wk	6 wk (with or without 2 wk gentamicin)
	Ceftriaxone *or*	4 wk	6 wk (with or without 2 wk gentamicin)
	Penicillin G *plus* gentamicin *or*	2 wk	Not applicable
	Ceftriaxone *plus* gentamicin *or*	2 wk	Not applicable
	Vancomycin[a]	4 wk	6 wk
Relatively resistant to penicillin (MIC >0.12 to <0.5 μg/mL)	Penicillin G *plus* gentamicin *or*	4 wk + 2 wk gentamicin	6 wk + 6 wk gentamicin
	Ceftriaxone *or*	4 wk	6 wk + 6 wk gentamicin
	Vancomycin[a]	4 wk	6 wk
Resistant to penicillin (MIC ≥0.5 μg/mL) (includes *Streptococcus* spp. and *Abiotrophia, Granucatella, Gemella* spp.)	Penicillin G (or ampicillin) *plus* gentamicin *or*	Duration to be determined in consultation with infectious diseases specialist	6 wk + 6 wk gentamicin
	Ceftriaxone *plus* gentamicin *or*		6 wk + 6 wk gentamicin
	Vancomycin[a]		6 wk
ENTEROCOCCI			
Susceptible to penicillin	Ampicillin (or penicillin) *plus* gentamicin[b] *or*	4–6 wk[d]	6 wk + 6 wk gentamicin[b]
	Ampicillin *plus* ceftriaxone[c]	6 wk	6 wk
Resistant to penicillin, susceptible to vancomycin			
β-lactamase producer	Ampicillin –sulbactam *plus* gentamicin[b]	6 wk	6 wk
Intrinsic resistance	Vancomycin *plus* gentamicin[b]	6 wk	6 wk
Resistant to vancomycin	Linezolid or daptomycin	> 6 wk	> 6 wk
STAPHYLOCOCCI			
(*Staphylococcus aureus* or coagulase-negative staphylococci)			
Susceptible to oxacillin	Oxacillin (or nafcillin) *plus* gentamicin	4–6 wk[e]	≥6 wk + ≥6 wk rifampin + 2 wk

	(optional for 3–5 days[9])		gentamicin
	Cefazolin[f]	≥6 wk	≥6 wk + ≥6 wk rifampin + 2 wk gentamicin
Resistant to oxacillin	Vancomycin *plus* rifampin *plus* gentamicin	≥6 wk	≥6 wk *plus* ≥6 wk rifampin *plus* 2 wk gentamicin

[a] If unable to tolerate β-lactam agent.

[b] If resistant to gentamicin, can use streptomycin.

[c] If resistant to aminoglycosides, can use double β-lactam combination: ampicillin plus ceftriaxone.

[d] Duration of therapy 4 weeks if symptoms <3 months, and 6 weeks if symptoms >3 months.

[e] Recommendation for children is 4−6 weeks[9] and for adults ≥6 weeks.[1]

[f] Nonanaphylactoid penicillin allergy; recommendation for adults.

MIC, minimal inhibitory concentration.

A Scientific Statement for Healthcare Professionals From the American Heart Association. Circulation 2015;132:1435−1486; and Baltimore RS, Gewitz M, Baddour LM, et al. Infective endocarditis in childhood: 2015 update. A Scientific Statement From the American Heart Association. Circulation 2015;132:1487−515.

TABLE 37.7

Doses of Commonly Used Antibiomicrobial Agents Recommended to Treat Infective Endocarditis

	Total Daily Dose[a,b]		
Antimicrobial Agent	**Children[c]**	**Adults[c]**	**Interval for Divided Doses[b]**
Ampicillin	200–300 mg/kg	12 g	4 hr
Cefazolin	100 mg/kg	6 g	8 hr
Ceftriaxone	100 mg/kg[b]	2 g[c]	24 hr
Penicillin (PCN) G			
If native valve and PCN-susceptible (MIC ≤0.12 μg/mL)	200,000 U/kg	12–18 million U	4 hr
If native valve and PCN-resistant (MIC >0.12 μg/mL)	300,000 U/kg	24 million U	4 hr
If prosthetic material	300,000 U/kg	24 million U	4 hr
If enterococci PCN-susceptible	300,000	18–30	4 hr

	U/kg	million U	
Gentamicin[d]	3 mg/kg	3 mg/kg	24 hr or 8–12 hr
Oxacillin, nafcillin	200 mg/kg	12 g	4–6 hr
Rifampin	15–20 mg/kg Max: 900 mg	900 mg	24 hr if oxacillin susceptible 8 hr if oxacillin resistant
Vancomycin[e]	40–60 mg/kg	15–20 mg/kg	Children: 6–12 hr
		Max: 2 g/day	Adults: 8–12 hr
Daptomycin	Regimen in consultation with infectious diseases specialist		

[a] Doses are recommended for normal renal function.

[b] Dosage adjustment is necessary when renal insufficiency exists.

[c] Do not exceed maximum dose for large children and adolescents.

[d] Synergy target peak 3−4 μg/mL and target trough <1 μg/mL.

[e] Target trough 10−20 μg/mL.

MIC, minimal inhibitory concentration; PCN, penicillin.

Definitive Antibiotic Therapy: Drug, Dose, Duration

Recommendations for targeted treatment of endocarditis depend on the pathogen, in vitro susceptibility test results, site of endocarditis (right- versus left-sided), presence of a foreign body (e.g., prosthetic valve), need for surgery, and tolerability and toxicity of first-line therapy (see Tables 37.6 and 37.7).[1,135,136] When clinical experience is limited, such as with endocarditis caused by multidrug-resistant organisms, recommendations are based on case reports, expert opinion, or data from animal models.

Endocarditis of native valves caused by viridans streptococci (e.g., *S. sanguis, S. oralis, S. mutans)* or *Streptococcus gallolyticus* (formerly *S. bovis*) that are highly susceptible to penicillin (minimal inhibitory concentration [MIC] ≤0.12 μg/mL) can be treated with penicillin (ampicillin) or ceftriaxone[1] after blood cultures are negative. Short courses (2 weeks) of either penicillin or ceftriaxone with gentamicin can be considered in select patients with uncomplicated endocarditis and normal renal function without extracardiac infection. *S. pneumoniae* endocarditis should be treated according to specific β-lactam MICs (see Tables 37.6 and 37.7). Endocarditis caused by *S. pyogenes* can be treated with penicillin or ceftriaxone, and endocarditis caused by group B, C, or G streptococci can be treated similarly with the addition of gentamicin for the first 2 weeks owing to increased MICs of penicillin and to bactericidal capacity of the combination. Endocarditis of prosthetic valves or other prosthetic material, such as shunts, requires longer courses than endocarditis of native valves.

Endocarditis due to enterococci susceptible to penicillin should be treated with a combination of penicillin (ampicillin) and an aminoglycoside (gentamicin or streptomycin) if susceptible to high concentrations.[1,137,138] Gentamicin dosing should be given in divided doses to achieve a trough concentration <1 μg/mL and a peak of 3 to 4 μg/mL. If the enterococcal isolate is resistant to ampicillin or the patient is allergic to penicillin, vancomycin plus an aminoglycoside is used, and trough levels of vancomycin should be 10 to 20 μg/mL. Vancomycin-resistant enterococcal endocarditis is treated with linezolid[139,140] or daptomycin. Recent clinical experience with daptomycin in Europe demonstrated successful treatment of 10 children with endocarditis.[141]

Patients with native valve endocarditis caused by methicillin-susceptible *S. aureus* (MSSA) should be treated with oxacillin or nafcillin, and those with MRSA or CoNS (e.g., *S. epidermidis* or *S. lugdunensis*) resistant to oxacillin should be treated with vancomycin (see Table 37.6). The addition of a second agent for treatment of staphylococcal endocarditis (generally gentamicin or rifampin) is not recommended for native valve endocarditis in adults.[1]

Recommendations for endocarditis of prosthetic valves or other prosthetic material caused by MSSA, MRSA, or CoNS include the addition of rifampin for the full course (at least 6 weeks) and gentamicin for the initial 2 weeks. Compared with streptococcal endocarditis, the treatment response of children with staphylococcal endocarditis is more protracted, with a mean of 2 days to sterile blood cultures, mean of 7 days to defervescence, and >14 days of fever in 17% of cases.[30] To date, glycopeptide-intermediate *S. aureus* (GISA), heterogeneous GISA, and glycopeptide-resistant *S. aureus* are rarely associated with endocarditis, and evidence-based strategies are limited. Quinupristin-dalfopristin, telavacin, trimethoprim-sulfamethoxadole (potentially with daptomycin), or ceftaroline may be useful.[1]

For endocarditis caused by enteric gram-negative bacilli, two bactericidal agents are chosen on the basis of in vitro susceptibility and generally include an expanded-spectrum β-lactam agent and an aminoglycoside or fluroquinolone.[1] The HACEK organisms frequently express β-lactamases and are slow growing, which makes susceptibility testing more difficult to perform. Thus treatment with a third-generation cephalosporin (ceftriaxone most commonly) is recommended.[1]

Management of endocarditis caused by *Candida* and *Aspergillus* spp. generally includes both medical and surgical approaches (discussed later) to optimize cure. Rare cases of fungal endocarditis have been managed successfully with antifungal therapy alone.[142,143] Traditionally, amphotericin or lipid amphotericin products have been used,[144] but caspofungin[145,146] and voriconazole[147] may be reasonable therapeutic alternatives. Unfortunately, pharmacokinetic studies with these newer agents have not been performed in neonates. “Lifelong” (long-term) fluconazole prophylaxis has been advocated in patients with fungal endocarditis to prevent relapses or as suppressive therapy in patients not deemed to be surgical candidates.[1]

Duration of antimicrobial therapy is based on the pathogen, susceptibility results, presence of prosthetic cardiac material, and clinical course. In children with native valve endocarditis due to viridans streptococci, 4 weeks of penicillin G alone (from the first negative blood culture) is effective and may be preferred because of limited experience with the 2-week regimen in young patients. Treatment for 6 weeks generally is recommended in “high-risk” situations, including infection due to relatively resistant streptococci or to enterococci, staphylococci, gram-negative bacilli, and in patients with intravascular prosthetic material. For the HACEK organisms, 4 weeks (if native valve) or 6 weeks (if prosthetic valve) of treatment is recommended. At least 6 weeks of therapy is recommended for patients with enterococcal endocarditis who had >3 months' duration of symptoms.[1] Even more prolonged courses are recommended for complicated endocarditis (e.g., intracardiac abscess) and in patients who have a slow response to therapy. Regardless of surgical intervention, fungal endocarditis should be treated with prolonged courses (≥6 weeks) of parenteral antifungal agents followed by oral fluconazole as describe previously.

Although no controlled trials document safety of outpatient therapy for endocarditis, clinically stable patients at low risk for complications (heart failure or embolic phenomena) can be selected who will have meticulous catheter care, regular home visits by an infusion nurse, easy access to a hospital if needed, and close follow-up with an experienced clinician.[148]

Antibiotics are almost always administered intravenously. Although there are reports of successful oral treatment of endocarditis, including with linezolid[139,149] and voriconazole,[147] this strategy has not been studied systematically and generally is not recommended. In addition, there are reports of successful management with antibiotics given orally for *S. aureus* endocarditis in intravenous drug abusers who are not candidates for parenteral therapy.[1]

Surgery

Studies in adult populations report lower mortality and fewer complications with surgery compared with medical therapy alone for some patients with endocarditis.[150] Critical review of studies reveals survivor and selection bias, confounding of differing types of endocarditis (e.g., native vs. prosthetic valve, right vs. left-sided) and indications.[1] Prudent surgical decision considers the host, the pathogen, persistent bacteremia, features of endocarditis (vegetation size, local cardiac complications, heart failure), and the occurrence or risk for embolic phenomena. The AHA expert advisory panel and the European Society of Cardiology define guidelines for surgery while emphasizing individualized management[1,8,9] (Table 37.8).[110,151–153]

TABLE 37.8

Considerations for Early Surgical Interventions[a] for Left-Sided Endocarditis[1,9]

Indication	Surgery
Heart failure from valve dysfunction from dehiscence, intracardiac fistula, or prosthetic valve dysfunction	Indicated
Heart block	Indicated
Annular or aortic abscesses or destructive penetrating lesions	Indicated
Endocarditis caused by fungi, mold, or multidrug-resistant organisms, e.g., vancomycin-resistant enterococci or multidrug-	Considered if native valve; indicated if

resistant gram-negative bacilli	prosthetic valve
Persistent infection, i.e., fever and positive blood cultures for more than 5–7 days (when other sites of infections are excluded)	Indicated
Recurrent emboli and persistent or enlarging vegetations	Reasonable
Mobile vegetation >10 mm and severe valve regurgitation	Reasonable
Relapsing prosthetic valve endocarditis	Reasonable
Mobile vegetation >10 mm and involving anterior mitral leaflet	Considered

[a] Defined as during initial hospitalization for endocarditis and before completion of antimicrobial therapy.

Although both guidelines recommend early surgery after a left-sided embolic event if vegetations persist, European guidelines recommend early surgery for silent events, whereas the American guidelines emphasize clinical events. The preservation of the native valve, particularly the mitral valve, is recommended when possible.[154] Although earlier recommendations were endorsed by the American Academy of Pediatrics,[5] collective data in children with endocarditis only recently confirms surgical survival rates similar to those of adults and low rates of recurrence.[155–157] In a review of 25 pediatric patients in Texas, surgery within 3 days of presentation was associated with a low risk for embolization.[156]

After embolic complications, surgical resection of an enlarging mycotic aneurysm in the cerebral vasculature is necessary if neurologic symptoms or bleeding ensue. Increasingly, early cardiac surgery is considered in patients with minor cerebral embolic events if imaging excludes intracranial hemorrhage. However, in patients with major ischemic stroke or intracranial hemorrhage, it is reasonable to delay valve surgery for at least 4 weeks to avoid hypotension and anticoagulation during surgery.

Delayed splenic rupture due to emboli is a potentially fatal complication of endocarditis. Large emboli to major blood vessels can lead to cold, painful, and pulseless extremities and require immediate surgical intervention.

Anticoagulation

There is no evidence that anticoagulation therapy with either aspirin or other agents is beneficial as an adjuvant therapy for endocarditis. However, controversy persists regarding management of patients receiving anticoagulation therapy who develop endocarditis because risk for hemorrhagic stroke is high.[1,5,158,159] It is reasonable to stop all anticoagulation therapy for at least 2 weeks in patients who have experienced a central nervous system event.[1] If cerebral hemorrhage has been excluded, anticoagulation during indicated cardiac surgery is acceptable.[160–163]

Complications

Complications of endocarditis include direct valvular damage, perivalvar extension of infection, and heart failure. Infection can disrupt valvular structure, causing leaflet fenestrations and chordae rupture, secondary valvular incompetence, and heart failure. Heart failure also can be caused by obstructive vegetations or new shunt lesions leading to extensive damage to cardiac structures. Perivalvar extension can result in endocardial abscesses, secondary fistulas, or pseudoaneurysms. Most abscesses in children are associated with native aortic valve and *S. aureus* endocarditis.[112] Clues to possible abscess formation include persistent fever and BSI; conduction abnormalities occur less frequently than is reported in adults with abscesses. Acute renal failure can result from immune complex deposition, renal infarction, hemodynamic instability, adverse effects of antibiotic therapy, or combinations thereof.

The risk for embolization varies from approximately 20% to 50% and may be higher if MRI is performed to detect silent lesions. The greatest risk for emboli is associated with *S. aureus, Candida,* HACEK organism, and *Abiotrophia* endocarditis.[1] Large (>10 mm) left-sided vegetations, particularly of the mitral valve, are associated with a higher risk for significant embolic events.[22,85,106,158,164–167] Most embolic events occur before or within the first 2 weeks of commensing therapy but also can occur after therapy has been completed.[158] Emboli from right-sided endocarditis can cause necrotizing pneumonia and prolonged fever; outcome generally is good with prolonged therapy. Left-sided endocarditis causes systemic emboli to the brain (more than half of embolic events), visceral organs, limbs, and coronary arteries. Brain emboli can result in stroke, mycotic aneurysms, and meningitis. Although the risk for neurologic events is ill-defined in children, 6% of pediatric patients with endocarditis were reported to have a stroke.[168] Visceral septic emboli can result in hemorrhage, infarct, or abscess.

Prognosis

Cure depends on the virulence of the infecting organism, the site of endocarditis, embolic phenomena, and the underlying clinical state of the host. More than 90% of children with native valve endocarditis due to viridans streptococci are cured,[21,83,84,164,169] whereas fungal endocarditis has the poorest prognosis, with overall cure rates <50%.[170]

Features associated with adverse outcome include multidrug-resistant pathogen, heart failure, presence of prosthetic cardiac material (especially artificial valve), cyanotic heart disease, previous episode of endocarditis, infant age, and vegetations >10 mm (especially left-sided). Persistence of fever for ≥2 weeks is associated with increased morbidity (myocardial abscesses, urgent cardiac surgery, healthcare-associated complications) and mortality.[21,30,96,171]

In some pediatric series, the prognosis of endocarditis has not improved in the modern era,[28,172] whereas in others, mortality rates are 4% to 5%.[27,173] In adults with healthcare-associated endocarditis, risk for in-hospital and 1-year mortality was increased compared with community-acquired endocarditis.[174] In an adult study, mortality was reduced from 18.5% to 8.2% when an interdisciplinary team of infectious diseases and microbiology specialists, cardiologists, and cardiac surgeons implemented a therapeutic protocol for endocarditis.[175]

Posttreatment Management

At completion of treatment, an echocardiogram should be performed to establish a new baseline for subsequent comparisons. Patients should be educated on signs and symptoms of relapse and should return for evaluation (including blood cultures) with any febrile illness. Daily dental hygiene and routine dental care are emphasized. Providers should be alert for heart failure and antimicrobial toxicity, including ototoxicity or *Clostridium difficile* infection.

Prevention

In 2007, the AHA modified antibiotic prophylaxis guidelines because existing evidence did not support widespread prophylaxis (see Chapter 7).[176] With targeting only of patients with the highest risk for endocarditis complications, recommended instances of prophylaxis are reduced, and antibiotic regimens are simplified.[5] In fact, the National Institute for Health and Clinical Excellence (NICE) of England and Wales halted recommending prophylaxis in 2008, instead emphasizing excellent dental hygiene and routine dental care.[177–180]

Using administrative pediatric hospitalization data from 2003 to 2010, endocarditis admissions declined without a change in the proportion of streptococcal infections following restricted 2007 guidelines.[47] Adverse consequences have not been noted in adults,[181,182] although one study showed an increase in streptococcal infections after 2007.[65]

Other Endocarditis-Like Intravascular Infections

Other types of infection can manifest as persistent BSI (bacterial or fungal). These include septic (or suppurative) thrombophlebitis, defined as venous thrombosis, inflammation, and bloodstream infection or, more commonly, *central line–associated blood stream infection* (CLABSI), defined as positive blood cultures in a patient with a central line and no other source for bacteremia.[183] Septic thrombophlebitis is a rare cause of hospital admissions (0.12%) in children, likely owing to improvements in catheter insertion and maintenance strategies.[184] In-hospital occurrence may be underrecognized.

Risk factors for septic thrombophlebitis include prolonged use (>96 hours) of intravascular catheters, surgical manipulation of a vessel, extension of infection from adjacent nonvascular structures, or severe burns. Septic thrombophlebitis can result from thrombi, fibrin clots, or biofilms forming on catheters, generally at the distal tip, or at the site of a surgical anastomosis or vascular prosthesis. Phlebitis results from trauma or irritation of the vessel wall. The clot or inflamed vessel becomes infected during bacteremia, from contaminated infusates, or from infected adjacent structures.[185] Suppurative thrombophlebitis develops if the vessel wall becomes infected. Progression of infection and inflammation can occlude the vessel, leading to a painful, enlarged, thickened, and tortuous vessel.

Nonvascular infections at adjacent sites can cause septic thrombophlebitis syndromes. Pharyngitis or peritonsillar abscess can cause Lemierre syndrome, that is, internal jugular vein septic thrombophlebitis.[186] Appendicitis, intra-abdominal infection, or abdominal surgery can cause pylephlebitis, that is, portal vein septic thrombophlebitis.[183] Septic abortions, pelvic surgery, or pelvic abscesses can cause pelvic vein thrombosis and infection.

Symptoms of superficial thrombophlebitis include fever, chills, induration, warmth, erythema, and tenderness of the infected vessel. In contrast, only about half of patients with central thrombophlebitis have signs of inflammation, and symptoms may not occur until several days after catheter removal.[187] Symptoms of portal vein thrombophlebitis include fever, right upper quadrant pain, anorexia, weight loss, and malaise.

Blood cultures usually are positive persistently, but pathogens also can be isolated from pus at the exit site, aspiration of the thrombosed vein, or the surgically resected vessel. *S. aureus* is the most common etiology of suppurative thrombophlebitis, but Enterobacteriaceae or fungi can be causative. Vaginal flora, including *Bacteroides* spp., streptococci, and gram-negative bacilli cause pelvic thrombophlebitis; and intestinal flora, including gram-negative bacilli and enterococci, cause intra-abdominal thrombophlebitis. Lemierre syndrome usually is caused by *Fusobacterium necrophorum* in singular or polymicrobial pathogenesis.

Septic thrombophlebitis can be life-threatening, particularly if diagnosis and treatment are delayed. Lesions are not vascularized, and penetration of antibiotics can be poor. Thus principles of therapy are similar to those for endocarditis. A fluctuant mass along the course of a previously catheterized vein can be aspirated, which frequently eliminates persistent BSI abruptly. Otherwise, treatment of suppurative thrombophlebitis requires antimicrobial therapy, catheter removal, and surgical consideration, including ligation of the infected vessel, excision of the infected segment, and potential anticoagulation if the thrombus extends.[183–185,188]

Complications of septic thrombophlebitis include sepsis, hypotension, and septic embolization. Septic embolization can provide the clue to the diagnosis. Lemierre disease, for example, can present with embolic cavitating pulmonary lesions. Superficial thrombophlebitis (manifesting as tenderness and inflammation) can complicate subperiosteal abscesses of the long bones.[189] Pulmonary emboli or osteomyelitis can complicate deep vein thrombophlebitis.[190] Superior vena cava syndrome can complicate septic thrombophlebitis of the thoracic central veins after catheterization.

Myocarditis

Christina A. Rostad, Joseph A. Hilinski

Myocarditis is an inflammatory disease of the heart muscle that may progress to dilated cardiomyopathy. The condition can manifest with a range of clinical presentations from nonspecific systemic symptoms to fulminant heart failure or sudden death. There is continued debate regarding the appropriate diagnosis, classification, and management of myocarditis.[1,2]

Etiology

Myocarditis can have a variety of infectious and noninfectious etiologies. For most cases in routine clinical practice, a specific cause is not found. Viruses are the most common causes of acute myocarditis in North America and Western Europe. Initial studies using serologic assays implicated enteroviruses, particularly coxsackievirus B serotypes 1 through 5, as important causes.[3,4] More recent studies using polymerase chain reaction (PCR) assays of endomyocardial biopsy specimens have confirmed the importance of enteroviruses in acute myocarditis (10%–20%)[5,6] and dilated cardiomyopathy (10%–30%).[7,8] Other viruses that are commonly identified by PCR in the myocardium include adenovirus,[5,6] parvovirus B19,[9] Epstein-Barr virus, and cytomegalovirus.[5] Myocarditis is also recognized as a complication during outbreaks of influenza, measles, mumps, and polio.[10-13] Human immunodeficiency virus[14] and hepatitis C virus[15] have been implicated in myocarditis, although the exact role each virus plays in causing disease is unclear.

Bacteria cause myocarditis less frequently than viruses. Invasion of the bloodstream by a bacterial pathogen, such as *Staphylococcus aureus, Neisseria meningitidis,* or *Salmonella* spp., can result in myocardial seeding and resultant microabscesses.[16-18] Myocarditis or myocardial dysfunction also can be a toxin-mediated complication of tetanus or diphtheria or can be caused by other bacteria such as *Borrelia burgdorferi* (occurring in up to 16% of children with early disseminated Lyme disease),[19,21] *Rickettsia* spp. (especially scrub typhus),[20] *Mycoplasma pneumoniae,* and toxin-producing staphylococci and streptococci.

Parasites are a major cause of myocarditis worldwide, with *Trypanosoma cruzi* (the causative agent of Chagas disease) being the principal cause in Central and South America.[22] Many additional agents have been reported to cause myocarditis in immunocompromised hosts, most importantly cytomegalovirus, *Toxoplasma gondii, T. cruzi, and Cryptococcus, Candida,* and *Aspergillus* spp.

Epidemiology

Myocarditis is diagnosed in up to 0.05% of pediatric hospitalizations in the United States.[23] Myocarditis has a slight male predominance and a bimodal age distribution that peaks in infancy and adolescence.[24] The incidence of myocarditis can coincide with the occurrence of epidemic enterovirus infections.[25] Enteroviruses cause approximately 10 to 15 million infections annually in the United States and can occur in any demographic population. In the US, enterovirus activity peaks in the summer and fall, although transmission is year-round in the tropics.[26] Chagas disease is endemic in Central and South America and is the most important cause of myocarditis in those regions.[22]

Myocarditis has been implicated in 4% to 20% of sudden cardiac deaths in autopsy series of young previously healthy adults.[27,28] Other studies using PCR techniques highlight the possible role of myocarditis in sudden infant death syndrome (SIDS). Enteroviruses, parvovirus B19, and adenoviruses are the most commonly detected viruses in cases associated with SIDS, although Epstein-Barr virus, cytomegalovirus, and *T. gondii* also have been detected.[29-31]

Pathophysiology

Pathogenesis

The pathogenesis of myocarditis has been gleaned in large part from animal models. These models suggest that both direct myocardial infection and host immune responses are important in the pathogenesis of disease. Viruses often initiate the process through binding to specific surface receptors on cardiac myocytes. A common coxsackievirus-adenovirus receptor has been identified on cardiac myocytes, which may in part explain the tropism of these viruses.[32] Infection and myocardial injury induce innate immune responses, most importantly proinflammatory cytokines tumor necrosis factor-α and interleukin-1β.[33] Mixed inflammatory cells subsequently infiltrate into the myocardium, and adaptive immune responses, including antigen-specific T lymphocytes and antibodies, are activated. At this stage, most patients clear the viral infection and recover from the acute illness with minimal sequelae. However, a subset of patients experience ongoing inflammation, which can lead to cardiac remodeling, fibrosis, myocyte necrosis, and ultimately dilated cardiomyopathy. Persistent viral replication[34] and autoimmune targeting of cardiac autoantigens[35] are postulated mechanisms of ongoing inflammation. Both $CD4^+$ and $CD8^+$ T lymphocytes are key mediators of myocardial damage and chronic inflammation.[36] Autoantibodies directed against a variety of cardiac antigens have also been implicated in this process.

Pathologic Findings

Several standardized criteria have been developed to diagnose myocarditis using histopathology or immunohistochemistry. The Dallas pathologic criteria, initially proposed in 1986, define myocarditis as histopathologic evidence of inflammatory cellular infiltrate with or without myocyte necrosis on conventionally stained heart tissue biopsy specimens.[37] Inflammatory infiltrates are further classified based on severity, distribution, and type as lymphocytic, eosinophilic, or granulomatous. However, more recent studies suggest these criteria lack sensitivity, in part owing to biopsy sampling site error and variability in interobserver interpretation.[38-40] The addition of immunohistochemical stains to characterize inflammatory cell infiltrates can improve diagnostic sensitivity and add prognostic value.[41] The World Health Organization and International Society and Federation of Cardiology Task Force on the Definition and Classification of Cardiomyopathies defines *myocarditis* as immunohistochemical evidence of mononuclear infiltrates ($CD3^+$ T lymphocytes or $CD68^+$ macrophages) with more than 14 cells/mm^2 on endomyocardial biopsy in addition to enhanced expression of HLA class II molecules.[42,43]

Myocarditis from bacterial, parasitic, and fungal causes can show specific findings with histologic staining. Bacterial and fungal infection result in polymorphonuclear cell infiltrates, which can be focal or organized into microabscesses. Trypanosomes can often be visualized in the biopsy specimens from patients with chronic Chagas disease. Giant cell myocarditis is a rare disorder of suspected autoimmune etiology in which multinucleated giant cells are found in the absence of granulomas.

Clinical Manifestations

Clinical manifestations of myocarditis are variable but usually arise in the setting of a systemic infection. The spectrum of cardiac manifestations ranges from subclinical cardiac dysfunction to heart failure, arrhythmia, and sudden death. A viral prodrome consisting of an influenza-like illness with fevers, myalgias, and gastrointestinal complaints often precedes cardiac involvement. This can be followed abruptly by myocarditis with hemodynamic collapse. Sudden death can be a presentation of myocarditis at any age, but particularly in infants and children.[44]

Infants and children frequently present with nonspecific symptoms, such as respiratory distress, feeding difficulties, irritability, and constitutional symptoms. Typical findings of heart failure also can be present, including tachycardia, a new-onset heart murmur or gallop, hepatomegaly, peripheral edema, and decreased peripheral perfusion. Chest pain may be present owing to concomitant pericarditis or, occasionally, to coronary artery spasm. In a retrospective review of 31 children with biopsy-confirmed or probable myocarditis, emergency department findings included preceding “viral illness” (77%), tachypnea or other respiratory difficulty (68%), chest pain (29%), symptoms related to hypoperfusion (23%), Kawasaki-associated symptoms (10%), and gastrointestinal complaints (7%).[45] Chest radiography abnormalities were observed in 55% of cases, and decreased ventricular function was present in 73% of cases. ST-segment or T-wave changes on electrocardiography were also noted in 67% of cases.[45]

Differential Diagnosis

There are many noninfectious causes of acute myocarditis. Most involve systemic inflammatory conditions, toxic or hypersensitivity drug reactions, envenomations, endocrinopathies, radiation, or transplant rejection (Box 38.1). Several cardiac diseases can manifest similarly to or in conjunction with infectious myocarditis. Pericarditis can be distinguished by the findings of precordial chest pain, signs of pericardial fluid, and absence of arrhythmia. Endocarditis can be distinguished by primary valvular abnormalities in the presence of positive blood cultures and echocardiographic evidence of vegetations. Myocardial infarction can have findings similar to myocarditis, whether the infarction is due to coronary artery atherosclerosis or to drug ingestions such as cocaine or methamphetamine. Primary and secondary cardiomyopathies, including genetic abnormalities of cardiac structure and electrical conduction, can also mimic acute myocarditis. The term *idiopathic* (or *lymphocytic* if characteristic lymphocytic infiltrates are seen) *myocarditis* is used to describe cases in which no causative agent is found.

Laboratory Findings and Diagnosis

A high index of suspicion is required to establish the diagnosis of acute myocarditis in children. If the diagnosis is considered, the initial evaluation should include chest radiography, electrocardiography (ECG), and echocardiography. Nonspecific laboratory findings associated with myocarditis include elevations in erythrocyte sedimentation rate, C-reactive protein, serum transaminases, brain natriuretic protein, and the MB isoform of creatine kinase.[45,46] Cardiospecific troponins are also elevated in most pediatric cases[46] and have higher sensitivity and specificity for detection of myocyte necrosis than other cardiac enzymes.[47]

ECG findings are abnormal in essentially all children with myocarditis, although they are highly variable. Common ECG changes in myocarditis include ST-segment or T-wave abnormalities (67%), axis deviation (40%), ventricular hypertrophy (30%), heart block (23%), infarction pattern (13%), and decreased ventricular voltages (7%).[45] Other related findings include tachycardia out of proportion to fever, conduction disturbances, and arrhythmias. Arrhythmias occur in nearly half of pediatric patients hospitalized with acute myocarditis, the most common of which are ventricular tachyarrhythmias.[46] Most ECG abnormalities resolve with recovery of acute illness over a period of 1 to 2 months.

Echocardiography is the most frequently used noninvasive technique to evaluate for acute myocarditis. Biventricular dysfunction on echocardiogram is the most powerful predictor for death or need for cardiac transplantation. Other echocardiographic findings commonly associated with myocarditis include valvular regurgitation, left ventricular dilation, and abnormalities of wall motion. Echocardiography also can exclude other causes of cardiac dysfunction, such as valvular vegetations or pericardial effusions. Repeated echocardiograms are useful to follow the evolution of disease, with persistent abnormalities suggesting progression to dilated cardiomyopathy.

Other imaging modalities that can be useful for diagnosing myocarditis include cardiac magnetic resonance imaging (MRI) and nuclear imaging techniques. Cardiac MRI has the ability to depict functional, morphologic, and tissue abnormalities such as edema, hyperemia, fibrosis, and necrosis. Because of its high spatial resolution and improved diagnostic accuracy, some have proposed the use of MRI as a noninvasive alternative to endomyocardial biopsy.[48] Consensus criteria have been published to describe the indications for cardiac MRI and to set forth diagnostic criteria based on MRI findings.[49] Nuclear imaging techniques can also detect the extent of myocardial inflammation and myocyte necrosis.[50] However, these techniques are not routinely used in the diagnosis of acute myocarditis because of limited specificity, spatial resolution, and radiation exposure.

Endomyocardial biopsy remains the gold standard for establishing the diagnosis of myocarditis, despite its limited sensitivity and specificity. In a large series of patients with suspected myocarditis, only 38% had positive biopsy results using the Dallas histopathologic criteria.[41] In general, biopsies performed within the first weeks of symptom onset have a higher yield than biopsies performed later in the course. Immunohistochemical stains and molecular techniques can also improve diagnostic sensitivity and enable identification of potential pathogens. However, in many cases the risks of biopsy outweigh the potential clinical and diagnostic benefits. The American Heart Association, American College of Cardiology, and European Society of Cardiology have issued a joint statement on the limited indications for and diagnostic role of endomyocardial biopsy in acute myocarditis.[51]

Specific diagnosis of infectious etiologies can be made in several ways. Pathogens can be isolated directly from myocardial tissue by culture or visualized using specific stains, or nucleic acid can be amplified using molecular techniques. Indirect associations can be made by detection of likely pathogens from other tissues or body fluids, such as the nasopharynx, throat, stool, or blood. In the acute setting, blood can be obtained for PCR analysis for common viruses such as enteroviruses, adenovirus, cytomegalovirus, and Epstein-Barr virus. Serologic assays showing a fourfold or greater rise of titers in paired sera, or a single positive immunoglobulin M assay, can also implicate specific infectious causes. Epidemiologic clues such as the season and geographic location may help narrow the differential diagnosis and focus the diagnostic evaluation.

Management

Supportive care is a key component of the initial management of patients with myocarditis. Although patients with mild myocarditis often recover with minimal intervention, those with heart failure or fulminant disease may require management in an intensive care setting. If congestive heart failure is present, patients should be managed according to established clinical guidelines. The American College of Cardiology Foundation and American Heart Association guidelines recommend routine use of angiotensin-converting enzyme inhibitors and β-blockers for patients with symptomatic heart failure and reduced left ventricular ejection fraction.[52] Diuretics and salt restriction are also indicated for patients with fluid retention and edema. Implantable cardioverter-defibrillators, pacemakers, and pharmacologic therapies may be indicated for patients with arrhythmias. Digoxin should be used with caution in patients with myocarditis owing to its association with increased myocardial injury and mortality in murine models.[53] Retrospective studies and case reports have demonstrated the benefits of ventricular assist devices and extracorporeal membrane oxygenation in pediatric patients for whom they are necessary.[54-56]

Specific infectious agents such as bacteria, fungi, or parasites should be treated with appropriate antimicrobial therapy. Diphtheric myocarditis should be treated with a combination of antitoxin and antibiotics. Clinical trials have not been performed to evaluate the efficacy of specific antiviral agents for viral myocarditis. However, if a treatable viral cause of myocarditis is established, antiviral therapy seems prudent.

Many studies have been performed to evaluate immune-modulating agents, including systemic corticosteroids, immune globulin intravenous (IGIV), interferons, and other immunosuppressive drugs for treatment of myocarditis; however, results remain controversial. The high incidence of spontaneous recovery after myocarditis necessitates that studies include a control group for accurate analysis of efficacy. In one of the largest trials of immunosuppressive agents, the Myocarditis Treatment Trial, 111 adults with biopsy-proven myocarditis were randomized to receive placebo or an immunosuppressive regimen consisting of prednisone plus either cyclosporine or azathioprine. No differences in mortality were found between the groups, and improvement in left ventricular function was identical at 28-week follow-up.[57] Another controlled trial evaluating prednisone (60 mg daily) for the treatment of unexplained dilated cardiomyopathy in adults showed initial improvement in left ventricular ejection fraction at 3 months of follow-up, but the benefit was not sustained at 6 or 9 months.[58] A meta-analysis, performed to review the use of immunosuppressive regimens for acute myocarditis in children, concluded that immunosuppressive therapy does not significantly improve pediatric outcomes.[59] For these reasons, and because of similar findings in other studies, immunosuppression should not be used routinely in the treatment of myocarditis.

The use of IGIV as therapy for myocarditis also has been controversial. A single retrospective cohort study of 21 children demonstrated high-dose IGIV (2 g/kg) was associated with improved left ventricular function and trends toward improved survival compared with historical controls.[60] However, a randomized controlled study in adults,[61] larger noncontrolled studies in children,[62,63] a systematic literature review,[64] and analyses of large national databases[23,24] have not demonstrated a consistent clinical benefit. Thus, the benefits of IGIV have not been fully substantiated, despite its widespread use in patients with pediatric myocarditis.[23,24] Interferon α and interferon β have demonstrated benefit in patients with dilated cardiomyopathy and myocarditis in small, single-center trials. However, larger trials are needed to confirm these findings.[65]

Complications

Complications of myocarditis include congestive heart failure, arrhythmias, cardiac rupture, sudden death, and progression to dilated cardiomyopathy. A large prospective study of 174 patients with biopsy-proven myocarditis demonstrated that biventricular dysfunction on echocardiography was the main predictor of mortality or need for heart transplantation.[66] Echocardiographic evidence of decreased ejection fraction (<30%), shortening fractions (<15%), left ventricular dilation, and moderate to severe mitral regurgitation also predicted progression to unremitting severe cardiac failure in a small pediatric study.[67] Other predictors of mortality include clinical signs and symptoms of heart failure, longer duration of symptoms, and younger age at presentation.[66] In a retrospective analysis of 41 children with myocarditis, 66% made a complete recovery, 10% had incomplete recovery, 12% died, and 12% underwent cardiac transplantation. Although medical management of this cohort varied, therapy was not significantly associated with patient outcomes.[62]

Prevention

Prevention of acute infectious myocarditis relies on prevention of underlying microbial causes. Hand hygiene, avoidance of fomites, and disinfection of surfaces are important measures to prevent transmission of many viral causes of myocarditis. Adherence to the standard immunization schedule, including administration of the seasonal influenza vaccine, can also prevent infections by specific pathogens.

Key Points

Epidemiology, Clinical Features, Diagnosis, and Management of Myocarditis

Epidemiology

- Viruses are the most common causes of myocarditis: enterovirus, adenovirus, parvovirus B19, human immunodeficiency virus, Epstein-Barr virus, cytomegalovirus, and other herpesviruses

- *Trypanosoma cruzi* (Chagas disease) is the most common cause in Central and South America

Clinical Features

- Clinical syndromes include subclinical cardiac dysfunction, heart failure, chest pain mimicking myocardial infarction, arrhythmias, and sudden death

- Symptoms often are nonspecific in children and include respiratory distress, feeding difficulties, chest pain, and fever in the setting of a viral prodrome

- Physical examination can show signs of heart failure such as tachycardia, hypotension, poor peripheral perfusion, hepatomegaly, and edema

Diagnosis

- The initial evaluation should include chest radiography, electrocardiography, and echocardiography

- Endomyocardial biopsy or cardiac magnetic resonance imaging can be useful in certain cases

- Specific diagnosis often is made by polymerase chain reaction, viral culture, and serologic tests

Management

- Supportive care is the mainstay of therapy
- Evidence is lacking to support routine use of immunosuppressants
- Immune globulin intravenous (IGIV) is administered commonly. Although a small retrospective pediatric study demonstrated benefit of IGIV, larger studies to date have not substantiated benefit.

Pericarditis

Christina A. Rostad, Joseph A. Hilinski

Pericarditis is inflammation of the pericardium and proximal great vessels. The etiologies of pericarditis are diverse and include infectious and noninfectious causes. Pericarditis may be acute, subacute, chronic, or recurrent in presentation. It may be the sole manifestation of a disease or part of a multisystem disorder. Pericarditis can manifest as cardiac tamponade with a fulminant, life-threatening process, as constrictive pericarditis from chronic disease, or as the incidental finding of an asymptomatic pericardial effusion. The European Society of Cardiology has published extensive guidelines on the diagnosis and management of pericardial diseases, which were updated in 2013.[1,2]

Etiology

Infectious pericarditis can be classified as benign, purulent, or granulomatous. Benign pericarditis is caused by viral infection, postinfectious, or postpericardiotomy syndromes; purulent pericarditis is caused by bacterial infection; and granulomatous pericarditis is caused by *Mycobacterium tuberculosis* and, occasionally, by fungal infection. Although the etiologic distribution varies among studies, in developed countries, upward of 80% of cases are idiopathic.[3] Noninfectious causes include neoplasia, uremia, hypothyroidism, cardiac injury, radiation, drug hypersensitivity, and autoimmune and autoinflammatory diseases.

Viral pericarditis commonly is associated with concurrent myocarditis, and its presentation ranges from subclinical infection to fulminant disease with severe hemodynamic manifestations. A viral etiology is assumed if a pericardial effusion is nonpurulent and if spontaneous resolution occurs. Enteroviruses, especially the coxsackieviruses, are considered the most common causes of viral pericarditis. Other viruses that are implicated commonly include adenovirus, parvovirus B19, human immunodeficiency virus (HIV), Epstein-Barr virus, cytomegalovirus, and other herpesviruses. Less commonly, influenza A and B, hepatitis B and C, mumps, and lymphocytic choriomeningitis are reported. Cytomegalovirus is an important cause of pericarditis in immunocompromised and HIV-infected people.[4]

Purulent pericarditis occurs when bacteria invade the pericardium as a result of bacteremia, contiguous spread from an intrathoracic infection, or direct inoculation from trauma or surgery. *Staphylococcus aureus* is the most common cause of purulent pericarditis, accounting for up to 44% of cases in children (Table 39.1).[5] Staphylococcal pericarditis often coincides with infection at other sites, including osteomyelitis, septic arthritis, skin infections, and pneumonia.[5–9] Historically, *Haemophilus influenzae* type b, *Streptococcus pneumoniae*, and *Neisseria meningitidis* also have been important causes of purulent pericarditis.[10–12] However, the incidence of invasive disease caused by these pathogens has declined in the postvaccine era. Other bacteria, including group A streptococci,[13] the *Streptococcus milleri* group,[14] *Salmonella* species, *Pseudomonas aeruginosa*, and other gram-negative bacilli, are implicated less commonly.[15] Rarely, anaerobic bacteria can cause pericarditis, either by hematogenous seeding (especially *Bacteroides fragilis*),[16] contiguous spread (especially pulmonary actinomycosis),[17] or as part of a polymicrobial infection.[16] HIV infection is an important predisposing factor worldwide for pericarditis, especially for bacterial and mycobacterial etiologies.[18]

TABLE 39.1

Causes of 163 Cases of Purulent Pericarditis, 1950–1977

Causative Organism	Number of Isolates (%)
Staphylococcus aureus	72 (44)
Haemophilus influenzae	35 (22)
Neisseria meningitidis	14 (9)

Streptococcus pneumoniae	9 (6)
Salmonella species	4 (3)
Escherichia coli	3 (2)
Other[a]	7 (5)
Unknown	17 (10)

[a] Includes isolates of *Klebsiella* spp., *Streptococcus pyogenes*, "Paracolon" spp., *Pseudomonas aeruginosa, Staphylococcus epidermidis, Bacteroides* spp., anaerobic streptococci, singly or in combination.

Data from Feldman WE. Bacterial etiology and mortality of purulent pericarditis in pediatric patients: a review of 162 cases. Am J Dis Child 1979;133:641.

Pericarditis caused by *M. tuberculosis* occurs in approximately 1% of cases of tuberculosis, either from lymphatic or bacteremic seeding or by direct extension from a pulmonary focus. Although an uncommon cause of pericarditis in developed countries, *M. tuberculosis* causes up to 70% of cases of pericarditis in Africa and other endemic regions.[19] Tuberculosis is also the most common cause of pericarditis in HIV-infected patients, accounting for 85% of cases.[20]

Pericarditis is occasionally caused by fungal infection, usually in the setting of surgery, instrumentation, neutropenia, or other immunosuppression. Fungi associated with pericarditis include *Candida, Aspergillus, Cryptococcus, Coccidioides, Histoplasma,* and *Blastomyces* spp. Less common infectious causes of pericarditis include *Mycoplasma* spp., *Ureaplasma urealyticum,* Rickettsiae, *Borrelia burgdorferi, Entamoeba histolytica, Toxoplasma gondii,* and *Toxocara canis.*

Epidemiology

The exact incidence and prevalence of pericarditis are unknown because epidemiologic studies are lacking. However, in a large series of children presenting to an emergency department with chest pain, 0.1% to 0.2% had pericarditis.[21] Approximately one third of pediatric pericarditis cases are classified as idiopathic or viral.[22] Idiopathic pericarditis is more common in adults than in children, and the incidence increases during adolescence.[23] In contrast, purulent pericarditis was once considered a disease of infancy and young childhood. However, with the advent of antibiotics and vaccines, the age distribution has shifted and the incidence has decreased substantially.[15] Bacteria are now rare causes of pericarditis, accounting for 5% or less of all pediatric cases.[22]

Tuberculous pericarditis is the most common cause of pericarditis in regions where *M. tuberculosis* is endemic. In developed countries, tuberculosis accounts for only 4% of cases of pericarditis and is more common among HIV-infected patients and immigrants from high-risk regions.[24]

Pathogenesis

The pericardium is a fibroserous sac that encompasses the heart and consists of an inner layer, the visceral pericardium, and an outer layer, the parietal pericardium. The visceral pericardium covers the surface of the myocardium with mesothelial cells, which reflect onto the parietal pericardium to form an enclosed sac containing pericardial fluid. The parietal pericardium contains a dense fibrous outer membrane that lines the mediastinal structures and attaches to the sternum, diaphragm, and adventitia of the great vessels. Both layers are 1 to 2 mm thick, with a space between them that contains 10 to 15 mL of pericardial fluid in healthy children and 15 to 35 mL in adults. The pericardium has independent blood supply from the internal mammary arteries and innervation from the vagus nerve. Primary functions of the pericardium are to provide the heart with structural support, lubrication by pericardial fluid, and protection from infection at adjacent sites.

In the setting of infection or acute injury, the pericardial response is nonspecific and limited to exudation of inflammatory cells, fluid, or fibrin. This process may result in a spectrum of disease ranging from dry pericarditis, to pericardial effusion with or without hemodynamic compromise, to fibrosis that may progress to constrictive or effusive-constrictive pericarditis. In effusive pericarditis, the accumulation of fluid within the pericardial sac may be tolerated if the effusion is small or if the rate of fluid accumulation is slow. However, large or rapid increases in fluid secretion can exceed the maximal resorptive capacity of the pericardium. When this occurs, compression of the cardiac chambers can acutely impair diastolic filling, leading to tamponade and death. Constrictive pericarditis, in contrast, generally is a late complication of chronic pericardial inflammation. Proliferation of fibrous tissue, neovascularization, and scarring result in a loss of pericardial elasticity and impaired cardiac filling. The combination of pericardial effusion under the pressure of a fibrosed pericardium is known as *effusive-constrictive pericarditis*.

Viral pericarditis typically manifests as dry or effusive pericarditis with a benign, self-limited course. Cardiotropic viruses can spread hematogenously and directly infect the pericardium and myocardium. Pericarditis can be the sole manifestation of viral infection or part of disseminated, multiorgan disease. Although pericarditis typically occurs as a single episode, up to 36% of pediatric patients experience recurrences.[25] The pathogenesis of recurrences is incompletely understood, but immunologic mechanisms are thought to be involved. Patients with recurrent pericarditis have increased rates of circulating antiheart, anti-intercalated disk, and antinuclear antibodies, which support the role of autoimmunity in this process.[26] Autoinflammatory diseases, especially familial Mediterranean fever and tumor necrosis factor receptor−associated periodic syndrome also have known associations with recurrent pericarditis and may underlie the pathogenesis in a minority of patients.

Purulent pericarditis arises from contiguous extension of an adjacent infection, hematogenous seeding, or direct inoculation from trauma or surgery. Contiguous extension of a pulmonary or pleural infection is an important cause of bacterial pericarditis, especially of pneumococcal and staphylococcal etiologies. Less common origins of bacterial pericarditis include suppurative mediastinal, subdiaphragmatic, and intracardiac infections. Bacteria also can be inoculated into the pericardium by hematogenous seeding, which commonly is the pathogenesis of *S. aureus* pericarditis. Additionally, intrathoracic surgical procedures can be complicated by purulent pericarditis, usually in the setting of sternal wound infection with osteomyelitis and mediastinitis. In these cases, *S. aureus, S. epidermidis, Candida* species, and nosocomial gram-negative bacilli usually are responsible.[8]

Tuberculous pericarditis can result from lymphatic spread, hematogenous (miliary) seeding, or rarely by direct extension of pulmonary disease. Granulomas containing *M. tuberculosis* initially develop in the pericardium and are followed by serous or serosanguineous effusion containing lymphocytes and monocytes. Healing of tuberculous pericarditis results in deposition of fibrin and collagen, which often leads to constrictive or effusive-constrictive pericarditis.

Clinical Manifestations

Pericarditis causes a variable spectrum of clinical manifestations. The most common presenting symptom is chest pain, which is reported in nearly all pediatric cases.[25] Pericardial chest pain may be felt over the entire precordium, to the left side over the trapezius ridge, and over the scapula. The pain may radiate down the arm and may be aggravated by movement. Chest pain generally is worse when supine and relieved when sitting forward. It is more common in acute infectious pericarditis than in chronic, indolent forms. Pain may be unrecognized in young children, who are more likely to present with irritability and respiratory distress.

Other symptoms of pericarditis in children include fever, respiratory, and gastrointestinal complaints. Fever is present in most children with pericarditis, although it is more common in those with purulent etiologies.[27] Respiratory symptoms include coughing, dyspnea, and exercise intolerance. Young children may additionally have tachypnea, use of accessory muscles of respiration, and grunting expiratory sounds as they splint the thoracic cavity. Gastrointestinal symptoms of pericarditis include abdominal pain, vomiting, and poor feeding. Because pericarditis frequently follows an upper respiratory tract infection, a preceding febrile or respiratory tract illness should alert clinicians to consider the diagnosis.

Examination of the heart can reveal tachycardia and muffled heart sounds caused by the surrounding pericardial effusion. A pericardial friction rub can be audible, especially when the effusion is small. Friction rubs are best heard during deep inspiration when a patient is kneeling or in the knee-chest position, leaning forward. Friction rub typically is a to-and-fro, high-pitched, loud, rasping sound heard throughout the cardiac cycle or limited to systole.

Clinical manifestations of tamponade include sinus tachycardia, elevated jugular venous pressure, peripheral vasoconstriction, reduced arterial pulse pressure, and pulsus paradoxus. Pulsus paradoxus represents a drop of more than 10 mm Hg in systolic blood pressure during inspiration due to decreased venous return to the heart. Other findings on examination of patients with pericarditis may include the Kussmaul sign (a rise or failure to fall of jugular venous pressure with inspiration) and the Beck triad (hypotension, muffled heart sounds, and elevated jugular venous pressure).

Differential Diagnosis

Chest pain and fever occur with pneumonia, empyema, myocarditis, and pleuritis. Although rare in children, myocardial infarction can also mimic symptoms of pericarditis. The differential diagnosis of pericardial effusion includes many noninfectious causes, most notably neoplasia, metabolic disease, collagen vascular disease, other systemic inflammatory disorders, trauma, irradiation, and drug hypersensitivity. Postpericardiotomy syndrome also is an important cause of pericardial effusion in the 6 weeks after cardiac surgery.[28]

Laboratory Findings and Diagnosis

The diagnosis of pericarditis is made on the basis of history, physical examination, and imaging studies. All patients with suspected pericarditis should undergo chest radiography, electrocardiography (ECG), and echocardiography.[1] The specific cause of pericarditis is best determined by direct examination of the pericardium or pericardial fluid. Analysis of fluid for complete cell count, glucose level, lactate dehydrogenase, and protein concentration is useful to support likely causes. Common laboratory findings include systemic leukocytosis and elevated acute phase reactants. Troponin I also can be elevated in children with pericarditis or myopericarditis.[29,30]

Chest radiography and ECG are important components of the initial evaluation. On chest radiograph, pericardial effusion causes an enlarged cardiac silhouette that is often globular in shape. The effusion can cause an epicardial “fat pad” sign on lateral views, which is a widened space anterior to the heart between the epicardial and the anterior mediastinal fat. Concomitant findings of pneumonia or findings suspicious for tuberculosis can be helpful etiologic clues. Typical ECG features of pericarditis include generalized ST elevation without reciprocal ST depression, except in leads V_1 and aVR. A few days into illness, ST segments return to baseline and T waves may flatten or invert. Low-voltage QRS complexes may be evident as a result of dampening of electrical activity by the pericardial effusion. Most ECG results normalize with resolution of disease, although T-wave abnormalities can persist.

Echocardiography is the most valuable tool for diagnosis and assessment of the severity of pericarditis. Echocardiography can differentiate between pericarditis, myocarditis, and endocarditis and can also assess for tamponade physiology. When pericardial fluid is present, both M-mode and two-dimensional echocardiography demonstrate a sonolucent space between the two layers of pericardium. M-mode is the more sensitive procedure and can reliably estimate the volume of pericardial effusion. Computed tomography (CT) and magnetic resonance imaging (MRI) are second-line imaging techniques that should be considered in scenarios with complex clinical presentation or inconclusive echocardiographic findings. CT and MRI provide superior anatomic resolution and characterization of inflammation, calcification, constriction, and intracardiac and extracardiac masses. The American Society for Echocardiography has published extensive recommendations to guide the use of multimodality cardiac imaging in patients with pericardial diseases.[31]

Microbiologic diagnosis of pericarditis is best established by direct examination of pericardial fluid or tissue. Standard diagnostic evaluation should include Gram, acid-fast, and fungal stains and cultures for bacteria, viruses, mycobacteria, and fungi. Special attention to rapid transport under anaerobic conditions is necessary to optimize recovery of anaerobic bacteria. Blood cultures should also be obtained and are frequently positive in patients with purulent pericarditis. If pericarditis results from extension from a contiguous focus, cultures of sputum, pleural fluid, or other foci may identify the pathogen.

Viral causes of pericarditis may be determined by culture, rapid antigen tests, serologic tests, and molecular genetic techniques. In general, a combination of these techniques is implemented to maximize diagnostic yield. Tissue culture should be inoculated for recovery of viruses from pericardial fluid and other foci of infection. Viruses detected in the respiratory tract, throat, or stool are often considered the likely cause of concomitant pericarditis. Paired serologic testing can also be helpful in the identification of certain viral etiologies. Because HIV remains an important cause of pericarditis, testing with a fourth generation HIV-1/2 antigen/antibody combination immunoassay is often prudent. Unfortunately, traditional diagnostic approaches have relatively low yield for detection of viral pathogens.[3,32] Although molecular techniques can increase sensitivity,[33,34] the clinical impact of viral polymerase chain reaction (PCR) testing is unclear because of the lack of specific antiviral therapeutics and the tendency for idiopathic cases to self-resolve. PCR may be helpful for purulent or constrictive pericarditis when bacterial or mycobacterial etiologies are suspected but cultures remain sterile.[33]

Recovery of mycobacteria or fungi is uncommon, but appropriate cultures for these agents should be performed in cases of granulomatous, constrictive, or effusive-constrictive pericarditis. When these agents are suspected, biopsy of the pericardium for histologic examination and culture has a higher yield than direct stain or culture of pericardial fluid alone. If tuberculous pericarditis is suspected, a tuberculin skin test or an interferon γ release assay also should be performed. PCR for *M. tuberculosis* performed on pericardial fluid can offer the advantage of rapid diagnosis, although sensitivity ranges from 30% to 64%.[35–37] Pericardial adenosine deaminase, interferon γ, and lysozyme are ancillary tests that may aid in the diagnosis.[37,38] Current guidelines recommend incorporating these nonspecific biomarkers into the evaluation when tuberculous pericarditis is suspected.[1]

Management

Patients who have a small pericardial effusion of apparent viral etiology may be conservatively managed with close monitoring, bed rest, and nonsteroidal anti-inflammatory drugs. However, the presence of a large effusion with tamponade or significant hemodynamic compromise requires immediate evacuation of fluid by pericardiocentesis or open drainage. Patients with suspected bacterial or fungal etiologies also should undergo prompt pericardiocentesis. The combination of pericardiocentesis and antimicrobial therapy in purulent pericarditis substantially improves mortality compared with antimicrobial therapy alone.[5] Although not routinely necessary, creation of a pericardial "window" may allow drainage of thick or rapidly accumulating fluid. Case series also suggest that instillation of a fibrinolytic agent may help liquefy pericardial exudate in cases of incomplete evacuation.[39] Pericardiectomy, the definitive procedure to remove the pericardium, is indicated for persistent or hemodynamically unstable restrictive pericarditis.[1] Although pediatric data are limited, case series suggest that pericardiectomy can be successfully performed in children with recalcitrant pericardial disease.[40,41]

Therapy with broad-spectrum antimicrobial agents should be initiated empirically if purulent pericarditis is suspected (Table 39.2). Bacterial pericarditis usually is treated with parenteral antimicrobial agents for 3 to 4 weeks. For areas with high rates of methicillin-resistant *S. aureus*, empiric therapy for purulent pericarditis should include vancomycin. Addition of a third-generation cephalosporin provides coverage for *S. pneumoniae*, *H. influenzae*, and *N. meningitidis*. Fungal pericarditis caused by disseminated candidiasis, aspergillosis, or dimorphic fungi *(Histoplasma*, *Coccidioides*, or *Blastomyces* spp.*)* usually requires prolonged antifungal treatment (see chapters on specific pathogens). Empiric antituberculous therapy using three or four drugs should be initiated if tuberculous pericarditis is suspected. Corticosteroids also should be considered, although the impact on outcomes is unclear; a large multicenter trial to assess corticosteroid effectiveness is underway.[42]

TABLE 39.2

Antimicrobial Therapy of Major Causes of Pericarditis

Causative Agent	**Antimicrobial Agent**	**Dosage (mg/kg/day)**
Enterovirus and other viruses	None[a]	—
Empiric therapy for purulent pericarditis	Vancomycin *or*	60
	Nafcillin[b] *or*	200
	Oxacillin[b] *plus*	200
	Cefotaxime *or*	200
	Ceftriaxone	100 (daily)
Therapy when agent is confirmed		
Staphylococcus aureus or *S. epidermidis*	Oxacillin *or*	200

(susceptible to methicillin)	Nafcillin	200
S. aureus or *S. epidermidis* (resistant to methicillin)	Vancomycin[c]	60
Haemophilus influenzae	Ampicillin (if susceptible) *or*	200–300
	Cefotaxime *or*	150
	Ceftriaxone	75 (daily)
Streptococcus pneumoniae (susceptible to penicillin) or *S. pyogenes*	Penicillin G	200,000–300,000 units
S. pneumoniae (intermediate to penicillin)	Cefotaxime *or* Ceftriaxone	300 mg (cefotaxime), 100 mg (ceftriaxone)
S. pneumoniae (highly resistant to penicillin)	Vancomycin	60
Mycobacterium tuberculosis[d]	Isoniazid	10–15 for 6 mo
	+	
	Rifampin	10–20 for 6 mo
	+	
	Pyrazinamide	30–40 for 2 mo
	+	
	Ethambutol	15–25 until susceptibility studies are available

[a] Cytomegalovirus may respond to ganciclovir or valganciclovir.

[b] Nafcillin or oxacillin should only be used if community rates of methicillin-resistant *Staphylococcus aureus* (MRSA) are low.

[c] Linezolid would be an alternative; some community-associated MRSA are susceptible to clindamycin.

[d] Addition of corticosteroids to antibiotic regimen can be considered (e.g., prednisone 1 mg/kg/day for 6–8 wk with taper). In communities where isoniazid-resistant *Mycobacterium tuberculosis* has been encountered, a four-drug initial treatment is recommended.

Complications

The major long-term complication of pericarditis is thickening and stiffening of the pericardial membrane leading to constrictive pericarditis. Although constriction is a rare complication of viral or idiopathic pericarditis, the incidence is much higher in patients with purulent, tuberculous, or neoplastic etiologies.[24] Pericardiectomy is the only definitive treatment for permanent constrictive pericarditis.[1] The most important negative prognostic factor after pericardiectomy is poor preoperative functional status.[41]

Recurrences complicate up to one third of cases of acute pericarditis. Conventional management in adults consists of nonsteroidal anti-inflammatory drugs for 10 to 14 days, colchicine for 6 months, and low-dose steroids for nonresponsive disease.[2]

Although the efficacy of colchicine in preventing recurrences is well established in adults,[43,44] controlled studies of its use in children are not yet available. Case series have described the benefits of immunomodulators[45–47] and immune globulin intravenous[48] in pediatric cases refractory to conventional therapy.

Prognosis

Historically, mortality rates of untreated purulent pericarditis have approached 100%. However, the combination of antimicrobial therapy and pericardial drainage has substantially improved patient outcomes. Of 162 children with purulent pericarditis reported in 1979,[5] mortality was 22% in children who had both antimicrobial therapy and drainage compared with 82% in those who received antimicrobial therapy alone. Young age and infection with *S. aureus* were independent risk factors for poor prognosis. More recent studies have reported improved patient outcomes with much lower mortality rates in the current era. In a 1994 report, 42 of 43 children with purulent pericarditis treated with both antimicrobial agents and drainage recovered completely.[7]

Key Points

Epidemiology, Clinical Features, Diagnosis, and Management of Pericarditis

Epidemiology

- One third of cases are idiopathic.
- Viruses are the most commonly proven infectious etiologies.
- Purulent pericarditis is rare in the postantibiotic era (≤5% of cases).
- *Staphylococcus aureus* is the most common bacterial etiology.
- Tuberculosis is the most common etiology in endemic regions and in HIV-infected people.

Clinical Features

- Symptoms include fever, chest pain, and shortness of breath.
- Physical examination findings include pericardial friction rub, muffled heart sounds, tachycardia, and respiratory distress.
- Signs of tamponade include tachycardia, hypotension, narrowed pulse pressure, elevated jugular venous pressure, and pulsus paradoxus.

Diagnosis

- The initial evaluation should include chest radiography, electrocardiography, and echocardiography.
- Specific diagnosis can be made by analysis of pericardial fluid or tissue with stains, polymerase chain reaction (PCR) testing, and cultures for viruses, bacteria, mycobacteria, and fungi.
- PCR, serologic, and rapid antigen tests improve diagnostic yield.

Management

- Viral or idiopathic pericarditis is managed by supportive care and nonsteroidal anti-inflammatory drugs.
- Purulent pericarditis requires both pericardial drainage and antimicrobial therapy.
    - Empiric antibiotics should include vancomycin because of the prevalence of methicillin-resistant *Staphylococcus aureus* plus a third-generation IV cephalosporin.
    - Duration of therapy with IV antibiotics usually is 3 to 4 weeks
- Cardiac tamponade requires emergent pericardial drainage to

prevent progression to obstructive shock and death.

- Pericardiectomy is indicated for persistent or hemodynamically unstable restrictive pericarditis.

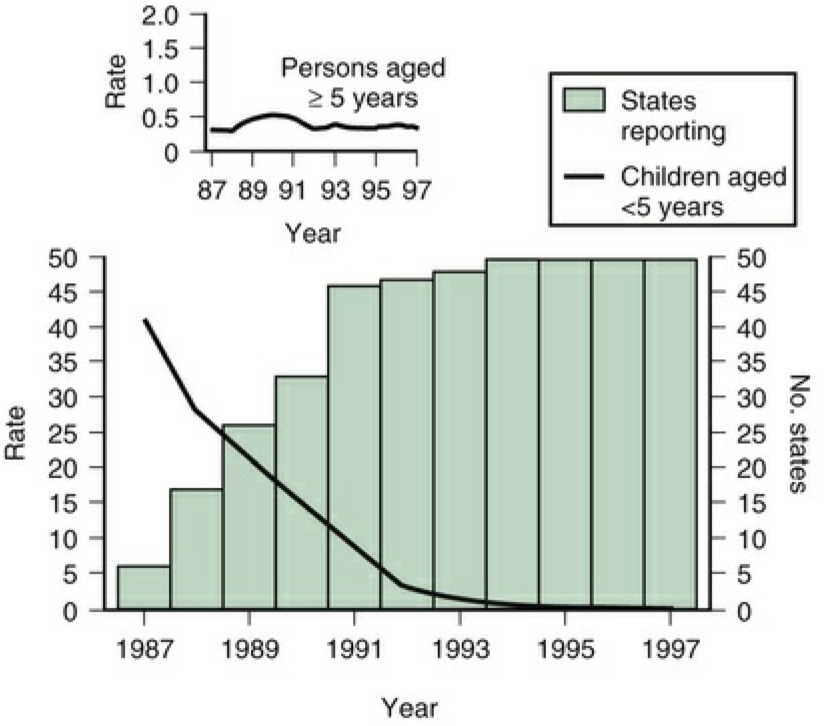
Acute Bacterial Meningitis Beyond the Neonatal Period

Suresh Kumar Panuganti, Simon Nadel

Etiologic Agents and Epidemiology

In otherwise healthy children, the three most common organisms causing hematogenously acquired acute bacterial meningitis worldwide are *Streptococcus pneumoniae, Neisseria meningitidis,* and *Haemophilus influenzae* type b (Hib). Previously, Hib accounted for up to 48% of all bacterial meningitis cases in United States[1]; however, the introduction of the Hib conjugate vaccination program led to a dramatic reduction in the incidence of Hib meningitis. In surveillance studies conducted by the Centers for Disease Control and Prevention (CDC), the incidence of Hib disease declined by 95% from 1987 to 1993 in children younger than 5 years (41 cases per 100,000 in 1987 to 2 per 100,000 in 1993) (Fig. 40.1).[2] Similar data from 1997 indicated a further decline to 1.3 cases per 100,000,[3] and there was a further decline to 0.11 cases per 100,000 in 2008.[4] The incidence also has decreased markedly in other areas of the world where Hib conjugate vaccines have been implemented for universal use in infants.[5,6] Currently, Hib accounts for only 7% of meningitis cases in the US, predominantly in unvaccinated adults[1] and in children who have not completed the primary immunization series.[4,7]



* Per 100,000 children age <5 years

† Per 100,000 persons age ≥5 years

§ Because of the low number of states reporting surveillance data during 1987–1990, rates for those years were race-adjusted using the 1990 U.S. population

FIGURE 40.1 Incidence of invasive *Haemophilus influenzae* disease among children younger than 5 years and the number of states reporting *H. influenzae* surveillance data to the National Notifiable Diseases Surveillance System, 1987–1997, United States. Insert represents the incidence of invasive *H. influenzae* disease among persons 5 years or older. Rate is expressed as cases per 100,000 population. (From Centers for Disease Control and Prevention. Progress toward eliminating *Haemophilus influenzae* type b disease among infants and children—United States, 1987–1997. MMWR 1998;47:993.)

Pneumococcal and meningococcal (and previously *Haemophilus*) meningitis occurred more commonly during the winter. In 1994–1999, the annualized incidence of *S. pneumoniae* meningitis in children aged <2 years in the US was 7.7 per 100,000,[8] and 7 (4, 6B, 9, 14, 18F, 19F, and 23F) of >90 pneumococcal serotypes accounted for >80% of invasive disease in children in the US and other developed countries. Serotypes 5 and 1 also were prevalent in developing countries.[9] The incidence of invasive disease caused by vaccine serotypes of *S. pneumoniae* fell by >95% after the implementation of universal 7-valent pneumococcal conjugate vaccine (PCV7) in US infants in 2000,[10] from 80 cases per 100,000 population to <1 case per 100,000 by 2007.[11] The rate of hospitalizations for pneumococcal meningitis in infants decreased by 66%.[8] Between 2000 and 2010, the incidence of disease caused by nonvaccine serotype 19A increased, with many isolates resistant to β-lactam antibiotics, including penicillin and third-generation cephalosporins.[12,13] Universal implementation of PCV13 (including serotypes 1, 3, 5, 6B, 7F, and 19a) has led to decrease in vaccine serotype invasive disease and only modest further decrease in meningitis cases.[14]

Six serogroups of *N. meningitidis* are responsible for severe disease and meningitis: serogroups A, B, C, X, Y, and W-135.[15] Infection with *N. meningitidis* can be either epidemic or endemic,[16] and although most cases in the US are sporadic,[1] *N. meningitidis* is the only bacterium that can cause meningitis outbreaks in the US.[15] Throughout America and Europe, serogroups B, C, W, and Y account for most cases of meningococcal meningitis, and serogroup B is the leading cause of endemic meningitis in developed countries overall.[1,15,17] The annual incidence of *N. meningitidis* meningitis in children younger than 5 years was approximately 4 to 5 cases per 100,000 in 1980. The overall incidence of meningococcal disease had begun to fall in 2005 when quadrivalent (A/C/Y/W-135) polysaccharide-protein meningococcal conjugate vaccine (MCV4) was licensed and recommended in the US for adolescents beginning at 11 to 12 years of age and for persons 2 through 54 years of age who have an increased risk for invasive meningococcal disease.[18,19] During 2005–2011, an estimated 800 to 1200 cases of meningococcal disease occurred annually (0.3 cases per 100,000), with a further decline to 564 cases in 2013 (0.18 cases per 100,000). Since 2005, declines have occurred among all age groups and in all vaccine-associated serogroups.[20] In addition, incidence of disease attributable to serogroup B, a serogroup not included in the vaccine, declined for reasons that are not known. Although disease incidence is at a historical low, the overall case-fatality rate remains at 10% to 15%, and 11% to 19% of survivors have long-term sequelae.[20] A novel protein and outer membrane vesicle–based vaccine against serogroup B meningococcus has recently been licensed in Europe. This vaccine and a protein-based vaccine have been licensed in the US and recommended for use in specific people and settings (see Chapter 6).[21]

The epidemiology of bacterial meningitis in the United Kingdom has changed dramatically in the past two decades after the introduction of vaccines to control Hib, serogroup C meningococcus, and some types of pneumococcus. After implementation of serogroup C MCV (MenC vaccine) in 1999, there was an approximate 80% reduction in serogroup C disease within 2 years.[22] Serogroup B meningococcus is now the most common cause of bacterial meningitis (and septicemia) in children and young people 3 months or younger.[23] The incidence of invasive meningococcal disease in the UK since 2004–2005 is depicted in Fig. 40.2.[24]

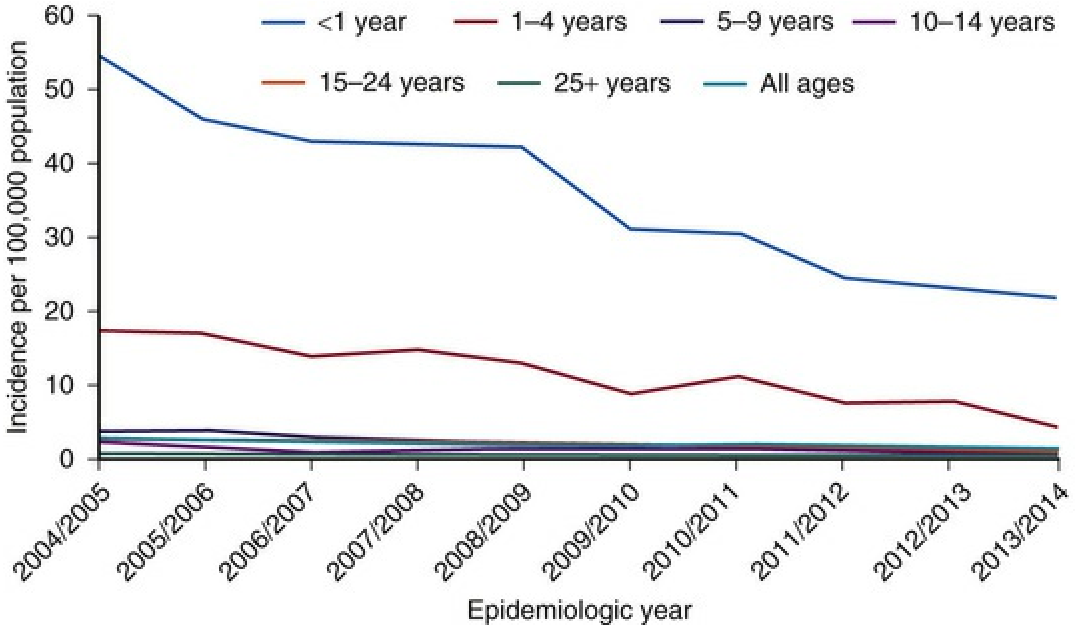


FIGURE 40.2 Incidence of invasive meningococcal infections in England and Wales by age group and epidemiologic year, 2004/05−2013/14.

Underlying conditions can be associated with increased risk for invasive infection, meningitis or infection due to particular pathogens, or both (Table 40.1). Children with a basilar skull or cribriform fracture and a cerebrospinal fluid (CSF) leak have greater risk for pneumococcal meningitis, as do children with asplenia (anatomic or functional) or human immunodeficiency virus (HIV) infection. Deficiencies in terminal components of complement lead to greater risk for meningococcal infection. Common causes of meningitis after penetrating head trauma or neurosurgery are *Staphylococcus aureus* and coagulase-negative staphylococci, streptococci, and gram-negative enteric bacilli, especially *Escherichia coli, Klebsiella* spp., and *Pseudomonas aeruginosa*. These organisms also are associated with meningitis related to a dermal sinus or embryopathy of the neurenteric canal. Nontypable *H. influenzae* meningitis is associated with immunoglobulin deficiencies, and *Listeria* meningitis with cellular immune defects; *Listeria* meningitis occurs occasionally in immunocompetent infants and children as well. *Salmonella* spp. rarely cause meningitis in immunocompetent children beyond early infancy. The presence of a ventriculoperitoneal shunt is a risk factor for meningitis and ventriculitis. Shunt contamination with gram-positive skin organisms at the time of surgery or subsequent tract infections, as well as ultra-abdominal contamination of ventriculoperitoneal shunts with gut organisms, can occur.

TABLE 40.1

Underlying Conditions and Organisms Commonly Associated With Bacterial Meningitis

Condition	Organism
Cerebrospinal fluid leak (otorrhea, rhinorrhea)	*Streptococcus pneumoniae, Haemophilus influenzae*
Dermal sinus tracts meningomyelocele	Staphylococci, gram-negative enteric bacilli, intestinal bacteria (related to site of defect)
Persistent complement deficiency	*Neisseria meningitidis*
Asplenia (anatomic or functional)	*S. pneumoniae, N. meningitidis, Salmonella* spp.
Renal transplantation, T-lymphocyte deficiency	*Listeria monocytogenes*
Otic fistula (stapes footplate, oval window; cochlear implant)	*S. pneumoniae*
Ventriculoperitoneal shunt	Staphylococci (coagulase-negative and *Staphylococcus aureus*), *S. pneumoniae, H. influenzae, N. meningitidis* (hematogenous), diphtheroids (e.g., contaminated shunt)
Antibody deficiency state (including HIV	*S. pneumoniae, N. meningitidis, H. influenzae* type b

infection)	
Penetrating trauma	Varies with nature and site of trauma (e.g., *Pasteurella multocida* after dog or cat bite, skin organisms after skull trauma, nasopharyngeal organisms after orbital or sinus trauma)
Surgery	Skin organisms, nosocomial pathogens

HIV, human immunodeficiency virus.

Isolation of an organism other than pneumococcus, meningococcus, or Hib or isolation of an unusual serotype or a vaccine-preventable organism in a vaccinated individual from the CSF of a child older than 2 months requires an explanation, with evaluation for unusual host susceptibility such as an anatomic abnormality or immunologic disorder.[25] Children with recurrent pneumococcal or meningococcal infections also should undergo thorough investigation, including neuroimaging and immunologic evaluation, with measurement of complement studies. Patients with cochlear implants, especially using a positioner device, have a >30-fold increased incidence of pneumococcal meningitis[26] and an increased risk for Hib meningitis.

Pathophysiology

Bacterial meningitis usually follows stepwise progression: bacterial colonization of the nasopharynx (or skin), mucosal invasion (or breach in skin barrier) leading to bloodstream infection, intravascular multiplication and passage through the blood-brain barrier, generation of inflammation within the subarachnoid space, and induction of neuronal and auditory cell damage.[27]

The three most common meningeal pathogens colonize the nasopharyngeal mucosa in 5% to 40% of children or adolescents at any given time; for Hib and *N. meningitidis,* fimbriae mediate adherence to epithelial cells; for *S. pneumoniae,* specialized surface components, such as surface adhesion proteins, may be important. These encapsulated organisms are able to evade local host defenses and either invade between epithelial cells (Hib) or pass through epithelial cells (*N. meningitidis*) to reach the subepithelial tissues, where the organisms can invade the vascular endothelium.[27] A viral upper respiratory tract infection can facilitate invasion by altering local tissue defenses. Increased hospitalization for invasive pneumococcal and meningococcal disease has been correlated with the viral respiratory season.[28,29] Intravascular replication leads to bacteremia and, with sufficient density of organisms, egress through the endothelium of the choroid plexus and cerebral capillaries into the ventricular fluid. A complex interplay between endothelial cells and microbial gene products appears to orchestrate the traversal of bacteria across the blood-brain barrier—transcellularly, paracellularly, or through infected phagocytes. For organisms that invade transcellularly, including *E. coli,* group B *Streptococcus*, and *S. pneumoniae,* the process is mediated by interactions with host receptors in the brain's microvascular endothelial cells.[30] For *N. meningitidis,* invasion is mediated by the outer membrane protein Opc invasin binding to human fibronectin to attach and invade brain endothelial cells.[31] Organisms multiply quickly and spread throughout the subarachnoid space because of the lack of intrinsic host defenses within the CSF. The host inflammatory response to bacteria leads to many of the alterations in central nervous system (CNS) function and in the CSF that are characteristic of bacterial meningitis.

Communications between mucosal surfaces or skin and CSF that result from trauma or congenital malformations can lead to direct invasion of the CNS by bacteria. A fracture through the cribriform plate (CSF rhinorrhea), paranasal sinuses, or temporal bone (CSF otorrhea) provides entrance for respiratory tract organisms into the CNS. Penetrating injuries of the skull by sharp objects (toys, teeth) in younger infants or children can precede bacterial meningitis. Bacteria also can reach the CNS through congenital defects, such as a dermoid sinus tract, meningomyelocele, or fistula through the stapes footplate, oval window, or cochlear aqueduct. These defects should be sought in patients with recurrent bacterial meningitis or meningitis due to unusual organisms.[32] Bacterial meningitis also can be a complication of neurosurgery, spinal anesthesia, or placement of a ventricular shunt or external ventriculostomy device (see Table 40.1).[33]

The pathologic features of bacterial meningitis have been described in detail.[34,35] Increased brain weight and flattened convolutions are evidence of cerebral edema. Temporal lobe or cerebellar herniation can occur. The brain and spinal cord are covered with a purulent subarachnoid exudate that consists primarily of neutrophils, which also infiltrate the perivascular spaces of blood vessels in the outer layers of the cortex of the brain and connective tissue sheaths of cranial and spinal nerves. Endothelial cells of small subarachnoid arteries and veins are swollen, leading to narrowing of the lumen and microscopic changes within brain parenchyma consistent with ischemia. The interstitial tissue of the choroid plexus is infiltrated with neutrophils. Phlebitis, venous thrombosis, arteritis, and brain necrosis are pathologic changes noted at necropsy in children who had untreated bacterial meningitis for less than 3 weeks. The foramina of Magendie and Luschka can be obstructed by exudate, resulting in obstructive hydrocephalus; however, communicating hydrocephalus is more common. This exudate, rich in bacterial products and proinflammatory substances, also can traverse the cochlear duct to involve the auditory tissue. Complex molecular events are being assessed to better understand the precise mechanisms of brain damage resulting from bacterial meningitis.[27] It is currently believed that neuronal death is caused mainly by apoptosis through caspase-dependent and independent pathways.[36] High levels of tumor necrosis factor-α have been observed in CSF of patients with meningococcal meningitis when sample was obtained within 48 hours of symptom onset.[37] Index of release of cytokines and chemokines per cell was significantly higher in pneumococcal meningitis.[37] Levels of only interferon γ were significantly higher in patients with meningitis due to *S. pneumoniae* compared with *N. meningitidis*. Changes in these mediators and in interleukin-1β (IL-1β) and IL-6 are the best-studied inflammatory responses in patients with bacterial meningitis.[38–40]

The molecular mechanisms responsible for oxidant-induced neuronal injury in experimental pneumococcal meningitis are summarized in Figs. 40.3 and 40.4.[41]

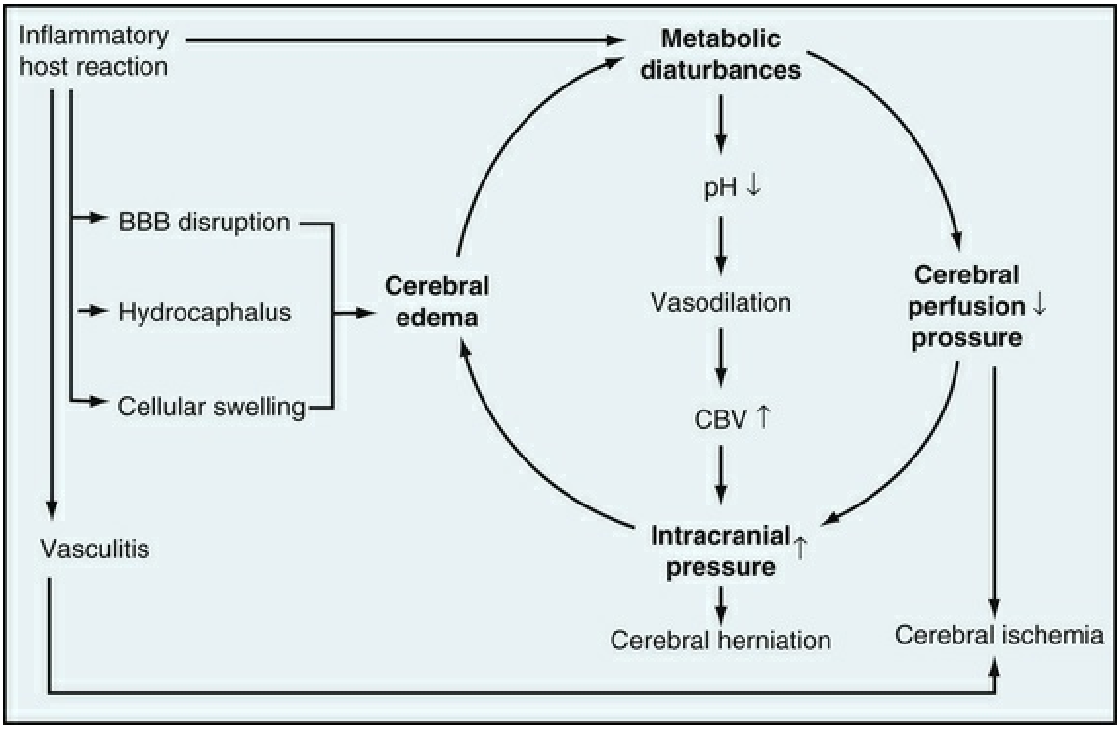

FIGURE 40.3 Pathophysiologic alterations leading to neuronal injury during bacterial meningitis. BBB, blood-brain barrier; CBV, cerebral blood volume. (From Scheld WM, Koedel U, Nathan B, Pfister HW. Pathophysiology of bacterial meningitis: mechanism(s) of neuronal injury. J Infect Dis 2002;186[Suppl 2]:S225–233.)

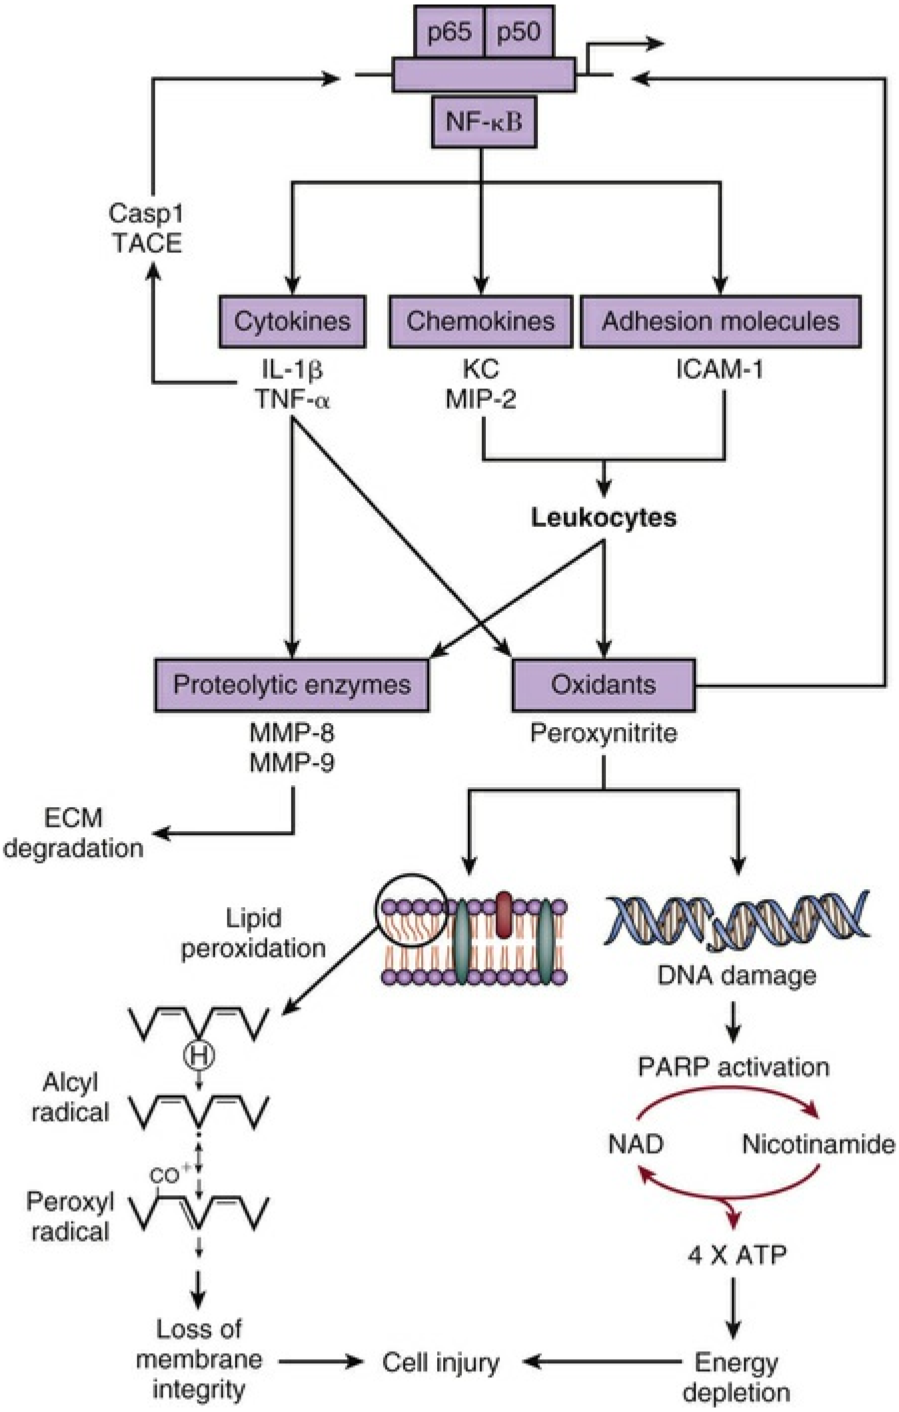

FIGURE 40.4 Mechanisms of brain damage in experimental pneumococcal meningitis. NF-κB, a transcriptional activator of many genes involved in the pathogenesis of bacterial meningitis, encodes host factors including proinflammatory cytokines, chemokines (e.g., interleukin [IL]-8), and adhesion molecules. The proinflammatory cytokines IL-1β and tumor necrosis factor (TNF)-α are synthesized as inactive precursors that are processed to mature active forms by proteases (caspase 1 [Casp1], also known as IL-1β–converting enzyme, and TNF-α–converting

enzyme [TACE]). IL-1β and TNF-α are potent activators of NF-κB. This process can lead to the uncontrolled expression of proinflammatory mediators and the increased expression of adhesion molecules both on the endothelium (e.g., intercellular adhesion molecule [ICAM]-1) and on neutrophils, leading to subsequent massive influx of leukocytes into the subarachnoid space. Once present, activated leukocytes release a complex variety of potentially cytotoxic agents including oxidants and proteolytic enzymes (e.g., matrix metalloproteinase [MMP]), which may contribute to tissue destruction. Also, peroxynitrite may cause brain damage through a variety of independent mechanisms. The best studied are attack of polyunsaturated fatty acids, leading to lipid peroxidation, and an alternative pathway that involves oxidant-induced DNA strand breakage and subsequent poly(adenosine diphosphate ribose) polymerase (PARP) activation, which initiates an energy-consuming intracellular cycle that ultimately results in cellular energy depletion and cell death. Both mechanisms likely contribute to cell injury during pneumococcal meningitis. ATP, adenosine triphosphate; ECM, extracellular matrix; KC, keratinocyte-derived chemokine; MIP, macrophage inflammatory protein; NAD, nicotinamide adenine dinucleotide. (From Scheld WM, Koedel U, Nathan B, Pfister HW. Pathophysiology of bacterial Meningitis: mechanism(s) of neuronal injury. J Infect Dis 2002;186[Suppl 2]:S225–233.)

Clinical Presentation

The clinical symptoms and signs of bacterial meningitis in children vary depending on the age of the child and duration of disease. Nonspecific findings include abnormal vital signs such as tachycardia and fever, poor feeding, irritability, lethargy, and vomiting.[1] An infant may become progressively more irritable and lethargic, refuse feeds, and manifest increasingly less interaction with caregivers. Older children may complain of headache, vomiting, back pain, myalgia, and photophobia; may be confused or disoriented; and may verbalize specifically that the neck is stiff or sore. Seizures are noted in up to 30% of patients before or soon after hospital admission and tend to occur more frequently in pneumococcal or Hib meningitis than in meningococcal disease. Complex seizures at the time of presentation increases the likelihood of meningitis more than twofold.[42] Focal neurologic signs or a reduced level of consciousness may be present. Coma on presentation, compared with irritability or lethargy alone, portends a worse prognosis.

On physical examination, the fontanel of an infant may be bulging, but this sign is neither highly sensitive nor specific for meningitis; the finding requires urgent evaluation. The infant demonstrates diminished activity and may show little interest in the environment. Kernig and Brudzinski signs and neck stiffness are more specific physical findings of meningeal inflammation and occur more commonly in children older than 12 to 18 months. The presence of meningeal signs increases the likelihood of meningitis, and absence decreases the likelihood.[39] No classical symptoms and signs, however, distinguish accurately children with or without meningitis.[16–43]

Cranial nerve VI palsy and, less commonly, cranial nerve III or VII dysfunction suggest increased intracranial pressure (ICP). Papilledema is uncommon in a child with uncomplicated meningitis and, if present, suggests another diagnosis (brain abscess, epidural or subdural empyema, another cause of increased ICP) or a complication of meningitis (venous sinus thrombosis). Unilateral weakness (hemiparesis) often is a result of ischemia or infarction, usually associated with vasculitis or cerebral artery spasm. Occasionally in an older child, ataxia is the major neurologic sign.

A petechial or purpuric rash and shock classically are associated with meningococcal septicemia (frequently coexisting with meningitis) but also can occur occasionally in infection due to Hib or *S. pneumoniae*. A maculopapular rash, which is difficult to distinguish from a common enteroviral exanthem, can occur in up to 15% of children with meningococcemia. Focal infections such as pneumonia, pyogenic arthritis, buccal cellulitis, pericarditis, and endophthalmitis can be present concurrently with bacterial meningitis; their presence should not discourage evaluation of CSF unless the severity of the condition warrants deferral of the lumbar puncture.

Children with bacterial meningitis usually have one of three patterns of illness: (1) nonspecific symptoms that progresses over 2 to 5 days; (2) rapidly progressive symptoms and signs over the course of 1 or 2 days; and (3) fulminant, rapid deterioration and shock early in the course of illness.[44]

Recognizing the uncommon infant or child with meningitis or other invasive bacterial infection among the large numbers of children evaluated for febrile illnesses requires expertise and a high index of suspicion, careful observation, and examination. The differential diagnosis in children with fever and alteration in CNS function includes other infections, such as viral and fungal meningitis, viral and protozoa encephalitis, focal brain or parameningeal abscess, Lyme disease, rickettsial disease, or infection. Noninfectious conditions also are considered, such as Kawasaki disease, collagen vascular disease and other vasculitides, acute disseminated encephalomyelitis, hypersensitivity to drugs (e.g., trimethoprim-sulfamethoxazole, immune globulin intravenous, antithymocyte globulin) and Reye syndrome.

Laboratory Findings and Diagnosis

A lumbar puncture to obtain CSF is necessary when the diagnosis of bacterial meningitis is considered. CSF should be collected from all cases with suspected meningitis before commencement of antimicrobial therapy, unless lumbar puncture is contraindicated or must be delayed (Table 40.2).[22] Antimicrobial therapy should not be delayed if lumbar puncture must be deferred. When considering acute infections, examination of CSF should include macroscopic, cytologic, and Gram stain examination, chemical determinations, culture and antimicrobial susceptibility testing, and testing such as by polymerase chain reaction (PCR) in certain circumstances.[45] By appearance, the CSF is normally clear like water. Hazy, cloudy, turbid CSF indicates the degree of pleocytosis, density of pathogen, or both.

TABLE 40.2

Contraindications for Lumbar Puncture in Children

Signs suggesting raised intracranial pressure	Reduced or fluctuating level of consciousness (Glasgow Coma Scale score <9 or a drop of ≥3 points) Relative bradycardia and hypertension Focal neurologic signs Abnormal posture or posturing Unequal, dilated, or poorly responsive pupils Papilledema Abnormal doll's eye reflex
Shock	Defer until stabilization
Extensive or spreading purpura	Defer until shock and coagulopathy
After convulsions	Defer until airway and breathing are stabilized
Coagulation abnormalities	Defer if results of coagulation studies are outside the normal range, platelet count is <100,000/mm^3, or patient is receiving anticoagulant therapy
Local superficial infection at the lumbar puncture site	Defer
Respiratory insufficiency, severe respiratory distress (nonintubated)	Lumbar puncture is contraindicated because of high risk for precipitating respiratory failure

Cerebrospinal Fluid Cytology, Chemistry, and Gram Stain

Although the typical CSF white blood cell (WBC) count in bacterial meningitis is >1000 cells/mm^3, few or no WBCs can be present in CSF in the early phase (usually of rapidly progressive infection). Bacterial meningitis usually leads to a neutrophil predominance in CSF, typically between 80% and 95%; 10% of patients with acute bacterial meningitis present with a lymphocyte predominance (defined as >50% lymphocytes or monocytes).[46] Presence of immature neutrophils is suggestive of bacterial infection. Viral meningitis (especially due to enterovirus) initially can elicit neutrophilic pleocytosis.

Traumatic lumbar puncture or intracerebral or subarachnoid hemorrhage can result in bloody CSF. Correction to assess actual CSF WBC pleocytosis is calculable, considering peripheral blood WBC count and red blood cell (RBC) mass.[47]

Normally, CSF in children older than 6 months shows <6 WBCs/mm^3 (with no polymorphonuclear leukocytes), glucose >45 mg/dL, and protein <45 mg/dL.[47] Values for 677 infants younger than 90 days with febrile illness but without meningitis have been reported.[48] In months 1, 2, and 3 of life, respectively, mean CSF WBCs were 6, 3, and 3 cells/mm^3 and protein 75, 59, and 40 mg/dL.[48] Effects of traumatic lumbar puncture of CSF values also have been studied, showing presence of approximately 2 WBCs/mm^3 and 1.1 mg/dL protein for every 1000 RBCs.[49] Only 2 of 122 children with proven bacterial meningitis in one study had CSF with <6 WBCs/mm^3.[50] The protein concentration is elevated (mean, 100–200 mg/dL), and the glucose concentration usually is depressed (CSF/serum ratio <0.6), but the degree of abnormalities depends on the offending organism as well as the cadence and duration of infection. Chemical meningitis, as can occur after posterior fossa neurosurgery, can have CSF findings similar to bacterial meningitis. In chemical meningitis, CSF glucose is rarely <10 mg/dL or WBCs >7500 cells/mm^3.[51] Occasionally, patients with rapidly progressive meningitis (especially due to *S. pneumoniae*) or with concurrent septic shock lack CSF pleocytosis, which is a poor prognostic sign.[1]

The CSF Gram stain smear is positive in up to 80% of patients with untreated bacterial meningitis, and when positive, it confirms meningitis and can raise suspicion of etiology. Gram stain is negative in cases of bacterial meningitis with abnormal CSF. Positive Gram stain can be present and growth negative in patients who received antimicrobial therapy before lumbar puncture.[1] Table 40.3 can guide a pathogen-based differential etiologic diagnosis based on characteristic CSF findings.

TABLE 40.3

Usual Cerebrospinal Fluid Findings in Children With Meningitis Caused by Various Microbial Etiologies

CSF Finding	Viral	Bacterial	Partially Treated Bacterial	Lyme	Fungal	TB
Leukocytes/mm^3	<1000	>1000[a]	>1000	<500	<500	<300
Neutrophils	20%–40%[b]	>85%–90%	>80%	<10%	<10%–20%	<10%–20%[b]
Protein (mg/dL)	N or <100	>100–150	60 to >100	<100	>100–200	>200–300
Glucose (mg/dL)	N[c]	UD to <40	<40	N	<40	<40
Blood-to-glucose ratio	N	<0.4	<0.4	N	<0.4	<0.4
Positive smear[d]	—	>85%[e]	≥80%	—	<40%	<30%
Positive culture	Rare	>95%	<90%	—	>30%[f]	<30%
PCR or other methods	Enterovirus, herpesvirus	16S RNA, bacterial DNA	16S RNA, bacterial DNA	*Borrelia burgdorferi* antibodies	*Histoplasma* and *Cryptococcus* antigen, India ink for *Cryptococcus*	*Mycobacterium tuberculosis*

[a] Fewer than 500 leukocytes can be seen in severe/rapid-onset pneumococcal meningitis.

[b] Neutrophil predominance can be observed in early stages of meningitis.

[c] Low glucose concentration can occur in meningitis caused by mumps and herpesviruses.

[d] Gram or acid-fast bacilli staining for bacteria or *Mycobacterium*, respectively.

[e] Fewer positive smears in *Listeria* meningitis because of lower bacterial inoculum.

[f] Better culture isolation rates for *Candida* than for *Histoplasma* or *Cryptococcus* organisms.

CSF, cerebrospinal fluid; N, normal; PCR, polymerase chain reaction; TB, tuberculosis; UD, undetectable.

Additional Tests

Latex Agglutination.

The reported sensitivities of latex agglutination of CSF samples from patients with untreated bacterial meningitis ranged from 78% to 100% for Hib meningitis, 59% to 100% for pneumococcal meningitis, and 22% to 93% for meningococcal meningitis.[1] Because of false-positive and false-negative test results and its limited value in management, latex agglutination testing is rarely used.

Urinary bacterial polysaccharide antigen may be detected readily in children with Hib and pneumococcal meningitis but also can be detected after immunization with the respective polysaccharide and conjugate vaccines. The test is rarely more discriminating than Gram stain and cannot be used to direct specific therapy.

Oral therapy before performing CSF examination rarely affects findings substantially for Hib meningitis[52]; effect is potentially more likely and is less well studied for pneumococcal or meningococcal meningitis. Antigen detection testing, with positive results, is most helpful in pretreated patients in whom CSF is abnormal but results of Gram stain and culture are negative.

Other Tests.

Measurement of serum C-reactive protein concentration may have value for detection of complications or treatment failures after serial measurements. A CSF leukocyte aggregation test has been suggested as a sensitive adjunctive screening tool for diagnosis of bacterial meningitis but has the limitation of low specificity.[53] Two meta-analyses suggest that an elevated CSF lactate level is a good distinguishing marker of bacterial meningitis.[54,55] However, CSF lactate level can be affected by a number of factors, including pretreatment with antibiotics (reducing the level) and seizures or cerebral hypoxia (increasing the level). Potential value awaits prospective evaluation.

Polymerase Chain Reaction Testing.

Primers are available for the simultaneous PCR detection in CSF of *N. meningitidis, S. pneumoniae,* and Hib. PCR testing on CSF can be valuable, especially when culture is negative in a pretreated patient.

In culture-confirmed cases, acute bacterial meningitis sensitivities of CSF detection for *H. influenzae*, *S. pneumoniae,* and *N. meningitidis* were 92%, 100%, and 88% respectively; specificity was 100%.[1] Sensitivity of PCR on CSF may be lower in pretreated compared with untreated patients.[1] PCR carried out on blood also may significantly increase diagnostic yield, especially in pretreated patients when there is a contraindication to lumbar puncture. Quantitative PCR showing high density of bacteria has been associated with unfavorable outcomes of both pneumococcal and meningococcal disease.[1]

Flow Cytometry.

Flow cytometry facilitates the detection of a large spectrum of cellular characteristics on a per-cell basis, determination of absolute cell numbers, and detection of rare events with high sensitivity and specificity.[56] Novel use of flow cytometry with a dedicated bacterial channel has been explored for diagnosis of meningitis.[57] Technical pitfalls include low number of cells in CSF, rapid decline (but variable by cell type) of leukocyte integrity within 30 minutes of sampling, and application after traumatic lumbar puncture.[56] A meta-analysis concluded that neutrophil CD64 expression could be a promising biomarker for diagnosing bacterial infection.[58] Large prospective studies are needed with validation of cutoff points established.

Blood Culture.

Blood culture is valuable in detecting the causative organism and establishing susceptibility patterns, especially when CSF cultures are negative. Reported positivity rates are 50% to 90% for *H. influenza*e, 75% for *S. pneumoniae*, and 40% for *N. meningitidis*.

The yield after commencement of antimicrobial therapy falls rapidly.[1] Culture recovery of *N. meningitidis* is enhanced by inoculation of broth without sodium polyanethole sulfonate. Aspiration of an inflamed joint, cellulitis, purpuric lesion, or purulent middle-ear fluid maximizes identification of the infecting organism and provides a pathogen for susceptibility testing. In children with meningitis after surgery or trauma, culture of a specimen protected from infected wounds is useful. Culture specimens obtained from puncture of sinus, middle-ear cavity, or mastoid bone can be useful when meningitis complicates these infections. Blood PCR assay can increase the diagnostic yield substantially, especially in patients pretreated with antibiotics.

Imaging Studies.

Nonenhanced computed tomography (CT) and magnetic resonance imaging (MRI) of patients with uncomplicated acute bacterial meningitis can be unremarkable.[59] CT often is performed to exclude contraindications for lumbar puncture; usefulness is limited to evidence of mass effect or hemorrhage and does not exclude the presence of raised ICP.[60,61] Raised ICP should be evaluated clinically.

Currently, MRI is the most sensitive imaging modality to assess extent of inflammatory changes in the meninges, brain abnormalities, and complications.[62] Leptomeningeal enhancement and distention of the subarachnoid space with widening of the interhemispheric fissure, small ventricles, and effacement of sulci can be reported to be an early finding in severe meningitis. Meningeal enhancement can be visible on contrast-enhanced CT and MRI but is nonspecific and is also present in carcinomatous meningitis, reactive meningitis (e.g., surgery, shunt, trauma), chemical meningitis (e.g., ruptured dermoid and cysticercoid cysts, intrathecal chemotherapy), and inflammatory conditions (e.g., sarcoidosis, collagen vascular disease).[62]

Neuroimaging can identify conditions that predispose to bacterial meningitis. Thus imaging is indicated in patients who have a history of head trauma, sinus or mastoid infection, and congenital anomalies. In addition, neuroimaging studies typically are used to identify and monitor complications of meningitis, such as hydrocephalus, subdural effusion, empyema, and infarction, and to exclude parenchymal abscess and ventriculitis. Identifying cerebral complications early is important because some complications, such as symptomatic hydrocephalus, subdural empyema, and cerebral abscess, may require prompt neurosurgical intervention.[63]

Management

Empiric antibiotic therapy should be begun urgently and without delay if lumbar puncture cannot be performed expeditiously. The choice of agents is based on the patient's age (an indication of etiologic pathogens) and underlying disease status and with knowledge of local antimicrobial susceptibility patterns and of dosing and pharmacodynamics of antimicrobial agents. When the infecting pathogen is isolated, antimicrobial therapy can be modified for optimal definitive treatment.

Antibiotics and dosages should be selected to produce CSF drug concentrations likely to be at least 8- to 10-fold greater than the minimal inhibitory concentration (MIC) required to inhibit and kill the pathogen in vitro, a level in animal models that predicts successful treatment.[64] For β-lactam antibiotics and vancomycin, the time during which the drug concentration exceeds the MIC appears to determine drug effectiveness (concentration-independent activity). For aminoglycosides and fluoroquinolones, effectiveness is determined by the ratio between the peak concentration or area under the curve of the antibiotic and the MIC of the pathogen (concentration-dependent activity).[65]

Antimicrobial Resistance

H. influenzae with ampicillin resistance due to β-lactamase production increased to 40% in the US by the mid-1990s.[66,67] Occasional additional isolates are ampicillin resistant as a result of alterations in penicillin-binding proteins or are chloramphenicol resistant because of production of chloramphenicol acetyltransferase enzyme.[66] Third-generation cephalosporins such as cefotaxime and ceftriaxone have excellent activity against all Hib strains and are comparable in efficacy but superior in rapidity of CSF sterilization compared with chloramphenicol for treatment of ampicillin-resistant Hib meningitis.[68–70]

The penicillin resistance of *S. pneumoniae* is a growing problem worldwide.[71] Before the mid-1980s, there were only scattered reports of bacterial meningitis due to penicillin-resistant *S. pneumoniae* throughout the world. Penicillin-nonsusceptible isolates had risen up to 40% in the US and as high as 60% in other countries by the 1990s.[72] In January 2008, the Clinical and Laboratory Standards Institute established breakpoints for *S. pneumoniae* depending on clinical site of infection (Table 40.4). For meningitis, strains are defined as nonsusceptible if penicillin MIC is ≥0.12 μg/mL.[73] *S. pneumoniae* infections with relative or high-level resistance to penicillin have alterations in penicillin-binding proteins and also can have reduced susceptibility to other β-lactam antibiotics. *S. pneumoniae* also can demonstrate resistance to multiple other classes of antibiotics (trimethoprim-sulfamethoxazole, chloramphenicol, and macrolides). Prevalence of resistance has fallen in many countries where PCV13 has been implemented.[74] In children's hospitals in the US, up to 20% of pneumococci recovered from children with invasive infections can be expected to show penicillin resistance. Penicillin or ampicillin even at high doses parenterally has been associated with treatment failure of meningitis due to pneumococci that are relatively or highly resistant to penicillin. Treatment failures for ceftriaxone or cefotaxime also can occur, usually with MIC ≥0.5 μg/mL.[75,76] Vancomycin and rifampin are active against cefotaxime- or ceftriaxone-resistant *S. pneumoniae*. Microbiology laboratories should routinely test all pneumococcal isolates from normally sterile sites for penicillin susceptibility. Screening can be accomplished with several methods, including oxacillin disk, Etest (AB Biodisk, Solna, Sweden), and commercial microtiter methods.[77]

TABLE 40.4

Clinical and Laboratory Standards Institute Guidelines for Interpretation of Susceptibility Testing of *Streptococcus pneumoniae* for Meningitis

	Minimal Inhibitory Concentration (μg/mL)					
Interpretation	**Penicillin**	**Cefotaxime/Ceftriaxone**	**Meropenem**	**Vancomycin**[a]	**Rifampin**	**Chl**
Susceptible	≤0.06	≤0.5	≤0.25	≤1	≤1	≤4
Intermediate	—	1.0	0.5	—	2	—
Resistant	≥0.12	≥2.0	≥1	—	≥4	≥8

[a] Absence or rare occurrence of resistant strains precludes defining results categories.

Pneumococcal isolates that are tolerant to β-lactam antibiotics and vancomycin have also been documented.[78] Because of defective autolysis, tolerant bacteria produce fewer cell wall–derived substances that cause meningeal inflammation, so CSF abnormalities can be mild.[79] As a result of tolerance, organisms can persist in CSF and cause relapse after treatment is stopped.

Aqueous penicillin G remains the agent of choice for meningococcal meningitis, although ampicillin and third-generation cephalosporins also are effective and are easier to administer. Clinical isolates of *N. meningitidis* with relative resistance to penicillin (MIC ≥0.125 μg/mL) have been reported.[80] Resistance is not associated with β-lactamase production but with alterations in penicillin-binding proteins. The clinical significance of this type of resistance in the treatment of meningococcal meningitis is unclear. Cephalosporin resistance is extremely rare.

Choice and Mode of Antimicrobial Therapy

Although a recent Cochrane review of preadmission antibiotics for suspected cases of nonsevere meningococcal disease included nonsubstantiated evidence, one randomized controlled trial indicated that a single dose of intramuscular (IM) ceftriaxone or long-acting chloramphenicol was equally effective, safe, and economical in reducing serious outcomes.[81]

The principles of antimicrobial therapy for acute bacterial meningitis include use of agents that penetrate well into CSF and attain appropriate CSF concentration, are active in purulent CSF, and are rapidly bactericidal against the infecting pathogen.[82]

Empiric therapy of suspected bacterial meningitis in the US is urgent administration of antibiotics parenterally: ampicillin *plus* cefotaxime for infants younger than 3 months, and vancomycin *plus* cefotaxime or ceftriaxone for children 3 months or older.[83] Ceftriaxone should not be used in premature infants or in infants with jaundice, hypoalbuminemia, or acidosis as ceftriaxone displaces bilirubin from albumin. Use in neonates with calcium-containing infusions can lead to cardiac precipitation and death.

After an organism has been identified and the antimicrobial susceptibility pattern is known, antibiotic therapy can be simplified or modified (Table 40.5).[46] Penicillin G or ampicillin can be used to complete therapy for pneumococcal or meningococcal meningitis due to susceptible organisms. Cefotaxime or ceftriaxone is continued for penicillin-nonsusceptible pneumococci that are susceptible to these agents (MIC ≤0.5 μg/mL).[83] Although many patients with isolates having third-generation cephalosporin MIC of 0.5 to 1 μg/mL have been treated successfully, treatment with cephalosporin alone usually is not recommended. It is prudent to repeat the CSF examination after 48 to 72 hours of therapy in patients with poor response or when infection is due to β-lactam–nonsusceptible pneumococci to document a negative Gram stain and sterile culture. If results of the second CSF Gram stain or culture are positive, or a pneumococcal isolate has an MIC of ≥1 μg/mL for extended-spectrum cephalosporins, vancomycin (if not begun previously) with or without rifampin should be added.[84] Rifampin should be added if the patient already is receiving vancomycin. Vancomycin penetration into CSF during meningitis can be unpredictable, and thus peak and trough serum values should be in the upper therapeutic range (35–40 and 10–15 μg/mL, respectively).

TABLE 40.5

Recommendations for Specific Antimicrobial Therapy in Bacterial Meningitis Based on Isolated Pathogen and in Vitro Susceptibility Testing

Microorganism	Standard Therapy	Alternative Therapies
Streptococcus pneumoniae		
Penicillin MIC <0.1 μg/mL	Penicillin G or ampicillin	Ceftriaxone or cefotaxime,[a] *or* chloramphenicol
Penicillin MIC 0.1–1 μg/mL[b]	Ceftriaxone or cefotaxime	Cefepime; meropenem
Penicillin MIC ≥2 mg/mL, *or* cefotaxime; *or* ceftriaxone MIC ≥1 mg/mL	Vancomycin + a third-generationcephalosporin[a,c]	Fluoroquinolone[d]
Neisseria meningitides		

Penicillin MIC <0.1 mg/mL	Penicillin G or ampicillin	Third-generation cephalosporin[a]; chloramphenicol
Penicillin MIC 0.1–1 mg/mL	Third-generation cephalosporin[a]	Chloramphenicol; fluoroquinolone; meropenem
Listeria monocytogenes	Ampicillin or penicillin G[e]	Trimethoprim-sulfamethoxazole
Streptococcus agalactiae	Ampicillin or penicillin G[e]	Third-generation cephalosporin[a]
***Escherichia coli* and other Enterobacteriaceae[g]**	Third-generation cephalosporin[a]	Aztreonam; fluoroquinolone; meropenem; trimethoprim-sulfamethoxazole; ampicillin
***Pseudomonas aeruginosa*[g]**	Cefepime[e] or ceftazidime[e]	Aztreonam[e]; ciprofloxacin[e]; meropenem[e]
Haemophilus influenzae		
β-lactamase negative	Ampicillin	Third-generation cephalosporin[a]; cefepime; chloramphenicol, fluoroquinolone
β-lactamase positive	Third-generation cephalosporin[a]	Cefepime; chloramphenicol, fluoroquinolone
Staphylococcus aureus		
Methicillin-susceptible	Nafcillin or oxacillin	Vancomycin; meropenem; linezolid; daptomycin
Methicillin-resistant	Vancomycin[f]	Trimethoprim-sulfamethoxazole; linezolid; daptomycin
Staphylococcus epidermidis	Vancomycin[f]	Linezolid

[a] Ceftriaxone or cefotaxime.

[b] Ceftriaxone/cefotaxime-susceptible isolates.

[c] Consider addition of rifampin if ceftriaxone MIC is >2 mg/mL.

[d] Moxifloxacin. No clinical data available; if used, many authorities would combine with vancomycin or a third-generation cephalosporin (e.g., cefotaxime or ceftriaxone).

[e] Addition of an aminoglycoside should be considered.

[f] Consider addition of rifampin.

[g] Choice of a specific antimicrobial agent must be guided by in vitro susceptibility testing.

Data from Tunkel AR, Hartman BJ, Kaplan SL, et al. Practice guidelines for the management of bacterial meningitis. Clin Infect Dis 2004;39:1267–1284.

Although rarely used in developed countries, chloramphenicol is an option for treatment of bacterial meningitis caused by ampicillin-resistant Hib or in a child with a history of anaphylaxis associated with penicillin or other β-lactam antibiotics. Because the pharmacokinetics of chloramphenicol are variable, serum concentrations should be monitored to ensure that safe and effective concentrations are achieved.[85] Ideal peak values are 15 to 30 μg/mL at 60 to 120 minutes after the completion of infusion.

Values exceeding 30 μg/mL are associated with bone marrow suppression; concentrations greater than 50 to 80 μg/mL have been associated with grey baby syndrome (which is not confined to infants) and impaired myocardial contractility. Several drugs affect the metabolism of chloramphenicol; concurrent administration of phenobarbital or rifampin lowers the chloramphenicol level, whereas administration of phenytoin raises the level.

Other potentially useful antimicrobial agents for the treatment of bacterial meningitis are cefepime and meropenem, both of which have been shown in limited studies to be equivalent to third-generation cephalosporins in the treatment of children infected with common meningeal pathogens.[86–89] The efficacy of these antibiotics against β-lactam−resistant pneumococci has not been defined, although they appear to be equivalent to the third-generation cephalosporins. Because of increased resistance to β-lactam agents, use of newer fluoroquinolones (gemifloxacin, moxifloxacin) and novel glycopeptides has been described in case reports. Linezolid appears to enter the CNS adequately, based on limited data in children and adults.[90,91]

A meta-analysis of randomized controlled trials involving severe infections mainly outside the CNS showed that fewer clinical failures were seen in infections treated with continuous intravenous infusion of antibiotics that act by time-dependent killing (e.g., β-lactams) and even with aminoglycosides that exhibit concentration-dependent killing.[91,92] Although continuous infusion can permit maintenance above the minimal bactericidal concentration during nearly 100% of the dosing interval, lower peak CSF concentrations are attained.[92,93] Knowledge of the relative importance of these findings and clinical observations in meningitis are lacking.

Monitoring During Therapy

Performance of complete blood counts during therapy is helpful for early detection of neutropenia, which is associated with β-lactam antibiotics and chloramphenicol; neutropenia is readily reversible when antibiotics are discontinued. Anemia is common in children with bacterial meningitis and also can be exacerbated by chloramphenicol. Ceftriaxone has been associated with immune-mediated, rapidly fatal hemolysis in patients with sickle cell disease, HIV infection, and leukemia.[94,95] Thrombocytosis (platelet count >750,000/mm^3) occurs frequently in patients with meningitis and has no apparent adverse clinical effect, and platelet counts need not be monitored. Diarrhea is the most common adverse effect of ampicillin and the extended-spectrum cephalosporins. Rashes, eosinophilia, and mild elevation in serum hepatic transaminase values can occur with any of these agents as well. Ceftriaxone occasionally has been associated with abdominal discomfort and pseudolithiasis ("sludge") in the gallbladder, as seen on ultrasonography[96]; this is reversed with discontinuation of the drug. Routine performance of MRI or CT has no benefit but is useful if the course is complicated, the pathogen is unusual, or reason for occurrence is sought.[97]

Duration of Therapy

The duration of antibiotic therapy for meningitis varies with the organism and the clinical response.[98]

When possible, therapy should be completed in the hospital to permit careful assessment of the response to treatment and to prevent complications of disease or therapy. Parenteral therapy can be completed at home for carefully selected older patients if meningitis is due to a fully susceptible organism and the patient has resumed normal activity. Ceftriaxone is approved for a once-daily dosing schedule, making it more convenient and perhaps less expensive than other agents for treatment of fully susceptible organisms. It is essential, however, to calculate and administer each dose correctly so that the patient is not treated inadequately for 24 hours because of a dosage or administration error.

Usual total duration of parenteral therapy for uncomplicated meningitis is pathogen specific: *H. influenzae* type b, 10 days; *S. pneumoniae*, 14 days; *N. meningitidis*, 7 days. A multicenter randomized trial in children with *H. influenzae, S. pneumoniae,* or *N. meningitidis* meningitis suggested equivalency of 5 days versus 10 days of therapy in selected, clinically well patients with no complications.[99]

Newer β-lactam monotherapies (cefepime, meropenem, ertapenem), fluoroquinolones (garenoxacin, gemifloxacin, gatifloxacin, moxifloxacin), and lipopeptide (daptomycin) antibiotics have been evaluated in the rabbit model of meningitis, with special emphasis on the potential role of combination treatments for synergy for resistant pathogens.[100]

For other organisms and neonates, see other specific chapters. In general, parenteral therapy is given for uncomplicated meningitis due to group B *Streptococcus* for >14 days; *Listeria monocytogenes* for 21 days; and gram-negative bacilli for ≥21 days. For theses pathogens, in neonates and those with complicated courses, neuroimaging and clinical course can aid decisions for more prolonged courses of therapy. Individual decisions are made for patients with suspected bacterial meningitis and negative CSF culture. Pretreatment drug is considered. For children 3 months or older, ceftriaxone or cefotaxime may be given for a total course of 10 days; for infants younger than 3 months, ampicillin plus cefotaxime may be given for ≥14 days.

Meningitis Due to Unusual Organisms

Gram-negative bacillary meningitis beyond the neonatal period occurs almost exclusively in compromised hosts and as a healthcare-associated infection.[101] Management is challenging.[102]

E. coli and *Klebsiella* spp. are the most common gram-negative enteric organisms outside of the neonatal period.[103] Combination therapy using an extended-spectrum cephalosporin or meropenem *plus* an aminoglycoside is usual empiric therapy, with consideration of susceptibility patterns of nosocomial organisms in hospital-associated cases.[104] Modifications are made after antimicrobial susceptibility test results (e.g., cefepime or meropenem *plus* an aminoglycoside for *Pseudomonas* meningitis). For patients with gram-negative bacillary meningitis, a repeat CSF specimen is obtained for culture at 24 to 48 hours after commencement of therapy and approximately every 48 hours thereafter until CSF sterilization is documented. Intrathecal administration of antibiotics is considered for unsuccessful sterilization. Rarely, an aminoglycoside is instilled directly into the ventricles (almost exclusively in postoperative, device-associated, or posttraumatic cases). This is best done through an Ommaya reservoir. Systemic treatment is continued for a minimum of 21 days or for at least 2 weeks beyond the first documented sterile CSF culture, whichever is longer.

Surgical drainage of wound infections after trauma or neurosurgery also is required, as is removal of contaminated devices. Imaging studies are performed in patients with gram-negative bacillary meningitis before the decision to terminate therapy, to assess the nature of cerebral involvement, necrosis, and loculated collections and the need for surgical intervention.

Meningitis caused by *S. aureus* is treated with nafcillin when the organism is susceptible (oxacillin does not adequately penetrate into CSF). Vancomycin is an alternative for patients who are allergic to penicillin or have a methicillin-resistant isolate. Adding rifampin to the antistaphylococcal regimen may be necessary if CSF Gram stain or culture results remain positive despite the use of agents active in vitro. Ampicillin plus an aminoglycoside is recommended for patients with meningitis due to susceptible strains of *Enterococcus* species. Vancomycin (with aminoglycoside) is used for ampicillin-resistant *Enterococcus* spp. Scattered case reports of successful therapy with linezolid and daptomycin in adults with meningitis caused by resistant staphylococci and enterococci have been published.[105–107] Ampicillin is the drug of choice for *L. monocytogenes* infection; data support the possible beneficial role of concurrent aminoglycosides, at least for the first several days of therapy. When infection occurs in a patient with a ventriculoperitoneal shunt, bacterial eradication is best accomplished by removal of the device coupled with antimicrobial therapy.

Supportive Care

Unless the patient is only mildly affected, initial supportive care of the child with bacterial meningitis is best provided in an intensive care setting, where the patient can be observed and monitored continuously.[108] Typically, most life-threatening complications of bacterial meningitis (septic shock, cerebral herniation, cerebral infarction, seizures, and inadequate ventilation) occur early in the course of treatment and require urgent intervention for optimal outcome. Early, protocolized, aggressive care by a consultant supervised pediatric team improves survival and outcomes.[109] Early tracheal intubation and mechanical ventilation should be considered for any child with evidence of respiratory compromise, threatened airway, ongoing shock, refractory seizures, or elevated intracranial pressure.[110]

A recent Cochrane meta-analysis supported use of maintenance, rather than restrictive fluids in the first 48 hours.[111] Fluid restriction is advised only in patients without clinical evidence of dehydration who have hyponatremia (suspicious inappropriate antidiuretic hormone secretion). If the patient is hypovolemic or in shock, additional intravenous fluids must be given accordingly. There is no evidence that fluid restriction reduces cerebral edema in children with bacterial meningitis. Maintenance of blood pressure within the normal range for age may require infusion of a vasoactive agent, such as noradrenaline.

Increased ICP is a major component of the pathophysiologic alterations of meningitis. In addition to elevation of the patient's head, some clinicians administer mannitol (0.5–2 g/kg) if clinical signs (apnea, bradycardia, sluggish pupils, or pupillary dilation) of extremely high intracranial pressure are detected. Immediate tracheal intubation and hyperventilation can be lifesaving if cerebral herniation is imminent. Seizures are controlled with standard anticonvulsants, such as benzodiazepines, phenobarbital, and phenytoin. Most seizures occur early in the illness and are generalized, usually can be controlled easily, and have limited prognostic significance. However, seizures that are focal, occur ≥48 hours after admission, or are difficult to control imply an underlying vascular disturbance (e.g., venous thrombosis, cerebral infarction), brain abscess, or subdural empyema and are associated with development of epilepsy and other neurologic sequelae.[112] Secondary stroke prevention should be considered.[113]

After adequate therapy begins, the duration of fever typically is 4 to 6 days. Recurrence of fever or persistence of fever beyond 8 days can be caused by several conditions (Box 40.1). Fever patterns should be evaluated carefully, although a specific explanation often is not found. It is unlikely that uninfected subdural effusions cause prolonged fever.

Adjunctive Therapy

Modulating the host response to infection may be beneficial in decreasing some of the sequelae of bacterial meningitis. In a recent Cochrane meta-analysis, adjunctive corticosteroid therapy in bacterial meningitis was associated with a nonsignificant reduction in mortality (17.8% vs. 19.9%;, risk ratio [RR], 0.90; 95% confidence interval [CI], 0.80–1.01; P = 0.07) but was associated with a reduction of hearing loss and neurologic sequelae.[114] Subgroup analyses for causative organisms showed that adjunctive corticosteroids reduced mortality in pneumococcal meningitis (RR, 0.84; 95% CI, 0.72–0.98), but not in Hib or meningococcal meningitis. Corticosteroids reduced severe hearing loss in children with Hib meningitis, but not in children with meningitis due to non-*Haemophilus* species.[114]

For potential benefit in bacterial meningitis, dexamethasone must be administered before or concomitantly with parenteral antibiotics, or within 4 hours after commencement if earlier administration is not possible.[22] Some clinical reports indicate that dexamethasone does not affect the bactericidal activity of a third-generation cephalosporin combined with vancomycin against highly resistant pneumococci.[115] Careful clinical assessment and second CSF evaluation are warranted in this situation.

Dexamethasone administration is associated with a rapid resolution of fever in treated patients, but a secondary transient rise in body temperature is observed in up to 40% of cases after the drug is discontinued.[114] Its administration has been associated rarely with severe gastrointestinal bleeding. The recommended dose of dexamethasone is 0.6 mg/kg/day in 4 divided doses for 4 days.[22]

In developing countries, novel adjuvant therapies are needed. The use of oral glycerol may be beneficial for children with bacterial meningitis through its action in increasing plasma osmolality, without inducing diuresis, leading to a reduction in cerebral edema and a presumed improvement in cerebral circulation and brain oxygenation.[116] A large randomized trial in Latin America showed a significant reduction in neurologic sequelae in children given adjuvant glycerol, or glycerol in combination with dexamethasone, compared with placebo.[117] Because glycerol is a relatively safe, inexpensive medication that can be administered orally, it may be especially attractive in resource-limited settings. Criticisms of the trial's design, in addition to a recent trial that failed to show benefit of glycerol in adults with meningitis, have led to questions about its use.[118]

Prognosis

With modern management, the mortality rate for bacterial meningitis in children caused by the three most common pathogens generally is <5% to 10%. Case-fatality rate and incidence of neurologic sequelae are greatest with pneumococcal meningitis. The neurologic sequelae of meningitis are listed in Box 40.2. Sensorineural hearing loss is the most common readily identifiable sequela. Hearing loss occurs in approximately 20% to 30% of previously healthy children after meningitis due to *S. pneumoniae* and in 5% to 10% of patients after meningitis caused by Hib or *N.*

meningitidis. Disturbances of balance are common in these children because the vestibular portion of cranial nerve VIII is affected. Hearing loss has been associated with CSF glucose concentration <20 mg/dL. Hearing should be tested before discharge or within 1 month after discharge in all children with bacterial meningitis so that if hearing loss is detected, potentially beneficial interventions are not delayed. Reversible deafness has been documented in some children tested at discharge and 4 to 6 months later.

Box 40.2

Neurologic Sequelae of Bacterial Meningitis

Sensorineural hearing loss

Ataxia

Hemiparesis

Quadriparesis

Epilepsy

Spinal cord infarction

Cortical blindness

Diabetes insipidus

Hydrocephalus

Behavioral disorder

Intellectual deficits

Acute hydrocephalus, as well as many sequelae related to cerebral vascular compromise, can improve with time. Hemiparesis can resolve several months to years after the event. Imaging studies demonstrate evidence of infarction in such patients, although these findings usually do not affect or change management.

Behavioral and academic problems are common, and more subtle consequences of bacterial meningitis may not be apparent for several years after infection. Although formal testing generally is not necessary, careful follow-up and assessment over time is essential; any concerns regarding school performance or behavioral disturbance warrant further investigation.

Prevention

Close contacts of patients with meningococcal disease should receive chemoprophylaxis with rifampin (5 mg/kg if <1 month of age, 10 mg/kg if ≥1 month of age; maximal dose 600 mg) twice daily for 2 days, started ideally within 24 hours of the exposure. A single oral dose of ciprofloxacin (20 mg/kg, maximal dose 500 mg) or azithromycin (10 mg/kg, maximal dose 500 mg) or a parenteral dose of ceftriaxone (125 mg IM if <15 years, 250 mg IM if ≥15 years) are suitable alternatives; the last is preferred for pregnant women. Immunization of unvaccinated individuals is also recommended depending on the serogroup and age.

Rifampin prophylaxis is recommended for all household contacts of an index case with Hib disease when at least one household contact is younger than 4 years and is unimmunized or incompletely immunized. Unvaccinated children younger than 5 years also should be given Hib vaccine as soon as possible.[119]

A marked reduction of pneumococcal meningitis in PCV7 vaccinated US children has been documented.[120–122] A trial of PCV9 conducted in African children with or without HIV infection was associated with 65% and 83% reductions, respectively, in invasive pneumococcal disease (IPD) caused by vaccine serotypes.[123] Universal implementation of PCV13 in the US has been associated with further reduction in incidence of IPD.

Epidemiologic studies identifying cases of invasive pneumococcal disease through Active Bacterial Core surveillance (ABCs) of the CDC before and after the implementation of PCV7 showed remarkable decrease in pediatric pneumococcal meningitis[124] and 76% reduction in all IPD cases in the US.[125] A decline in cases of pneumococcal meningitis in children younger than 2 years also was evident in Europe and the US after implementation of PCV7.[8] However, an increase in pneumococcal meningitis cases in children 2 years and older due to nonvaccine serotypes was noted in France.[126] Children younger than 2 years who are at high risk for developing invasive pneumococcal disease, such as patients with specific dysfunction (sickle cell disease, asplenia) and nephrotic syndrome, or who are at increased risk for meningitis, such as children with cochlear implants, also should receive the 23-valent polysaccharide vaccine (PPSV23) at 2 years of age.[127]

Mass campaigns using MCV have led to control of serogroup C meningococcal disease in the UK, Canada, Australia, Spain, Belgium, Ireland, and Iceland. Serogroup B disease, predominant in New Zealand, has been dramatically decreased, partly owing to the introduction of an outer membrane vesicle (OMV) vaccine. Polysaccharide vaccines were used in high-risk people in Saudi Arabia and Syria and in routine immunization in China and Egypt. For serogroup B, vaccine development has included protein vaccines based on meningococcal OMV, whereas more recently a range of conserved proteins, including factor H binding protein (fHBP), *Neisseria* adhesin A (NadA), and *Neisseria* heparin binding antigen (NHBA), have been used as vaccine components.

A 4CMenB vaccine (Bexsero), containing three recombinant proteins, and OMV derived from a serogroup B meningococcal strain (MenB) has been licensed in Europe, Australia, and the US for persons 2 months and older. A serogroup B fHBP vaccine (Trumenba) has been licensed in the US. Although recommendation for use of serogroup B vaccines in the US include certain at-risk populations and use during outbreaks,[128] vaccine has not been recommended for universal use because of current low burden of disease. The UK Joint Committee on Vaccination and Immunisation has taken a position to introduce this vaccine into the routine infant schedule in 2015.[23]

Since the introduction of the meningococcal C (MenC) vaccination program in the UK in November 1999, the vaccine schedule has undergone changes. In 2013, the UK recommended an adolescent booster dose to extend protection into early adulthood. In addition, because of the increase in incidence of serogroup W disease and high carriage among university students of serogroup Y, quadrivalent conjugated meningococcal vaccine (containing serogroups A, C, W, and Y) has been recommended in UK adolescents.[129] Other countries that introduced the vaccine in later years have followed similar schedule changes based on the experience of the vaccine in the UK. The MenC vaccine was introduced in Australia in 2003 as a single dose for all children younger than 12 months. Since 2013, the combined Hib and MenC conjugate vaccine, Menitorix, was added to the National Immunisation Program schedule at 12 months of age.[127]

Chronic Meningitis

Douglas Swanson, Christopher J. Harrison

Chronic meningitis is defined arbitrarily as persistent or progressive signs and symptoms of meningeal irritation and cerebrospinal fluid (CSF) pleocytosis lasting for at least 4 weeks without improvement. The symptoms of chronic meningitis vary, but most patients have a gradual onset of fever, headache, and vomiting. The 4-week timeframe is intended to avoid extensive evaluation for individuals with self-limited processes (e.g., acute or subacute meningoencephalitis, resolving acute meningitis). In most cases of prolonged meningitis, diagnosis and treatment occur before clinical symptoms have continued for 4 weeks; thus chronic meningitis is relatively rare.

Etiology and Epidemiology

There are many infectious (Table 41.1[1–31]) and noninfectious (Box 41.1[32–42]) causes of chronic meningitis. Several parameningeal infections also can manifest as chronic meningitis. The most common entities are shown in Box 41.2. The etiology and epidemiology of chronic meningitis can vary considerably, depending on a patient's geographic locality or underlying medical conditions. Individuals with an impaired immune system are at increased risk for developing chronic meningitis, and potential etiologies also are increased. The overall incidence of chronic meningitis is unknown because of limitations of the medical literature and differs for each etiologic agent. The literature consists primarily of case reports and case series, which contain demographic and diagnostic bias.[43–45] Furthermore, most case reports are of adults. Except for tuberculosis, there is a paucity of information regarding children with chronic meningitis. The history, physical examination findings, and laboratory test results may help identify the cause of chronic meningitis; however, an etiology is not found in about one third of cases.[43,44]

Main Features of Agents Causing Chronic Meningitis

Mycobacterium tuberculosis

Epidemiology.

Most tuberculous meningitis occurs in children between 6 months and 4 years of age.[1,46–50] Risk factors include close contact with contagious cases, travel to or residence in tuberculosis (TB) endemic areas, human immunodeficiency virus (HIV) infection, other viral infections (i.e., measles), malnutrition, and immunosuppression. Close contact with an adult with pulmonary TB disease can be established in 45% to 75% of children; however, the exposure history may not be elucidated initially.[1,46–50] African Americans and immigrants and adoptees from countries where tuberculosis is endemic account for a disproportionate number of cases of tuberculous meningitis in the United States.[51] Large epidemiologic studies including children and adults find that about 1% of tuberculosis disease involves the central nervous system (CNS).[52,53] However, children are at a higher risk for developing CNS tuberculosis. A review of pediatric tuberculosis cases in the US from 1993 to 2006 shows that meningeal infection accounted for 3.1% of all cases[54] and depended on age: 7.5% in those younger than 1 year, 3.5% for 1- to 4-year-olds, 1.4% for 5- to 9-year-olds, and 1.8% for 10- to 14-year-olds.[54]

Pathogenesis.

Tubercle bacilli are inhaled, enter the lung alveoli, are filtered into draining lymph nodes, and then are spread lymphohematogenously throughout the body. Meningitis develops when caseous lesions in the brain cortex or leptomeninges rupture into the subarachnoid space.[55,56]

Clinical Manifestations.

The clinical onset of CNS tuberculosis can be acute, but more often there is gradual progression of symptoms. CNS tuberculosis usually manifests as meningitis and less frequently as intracranial tuberculoma or a brain abscess.[1,46–51] Association with disseminated (miliary) tuberculosis is not uncommon. A compilation of 913 children from 6 retrospective case series of CNS tuberculosis identifies common presenting symptoms to be fever (72%), altered mental status (62%), vomiting (61%), seizure (47%), and headache (37%).[1,46–48,50,51] Apathy is common, and about 29% of children develop cranial nerve paresis.[1,46,48–51] In outcome studies totaling 847 children with CNS tuberculosis, 18% died and 46% had neurologic sequelae.[1,46–51]

Laboratory Findings and Diagnosis.

A careful history for tuberculosis risk factors in concert with clinical findings suggests the diagnosis. Abnormalities on chest radiograph consistent with TB are present in about 75% of cases, and tuberculin skin test (TST) is positive in about 50% of children.[1,46–51] Cranial computed tomography (CT) frequently reveals hydrocephalus and basilar enhancement.[1,46–51] CSF abnormalities can be modest initially but become progressively more abnormal with increasing duration of symptoms. The CSF leukocyte count typically ranges from 10 to 500 cells/mm^3 and can briefly show polymorphonuclear cell predominance, but usually there is lymphocytic predominance. The CSF glucose level typically is low (frequently <20 mg/dL), and the protein level often is very elevated (>400 mg/dL). Reported positivity of acid-fast bacilli (AFB) stains of CSF range from 5% to 51%. The likelihood of detecting organisms on AFB stain depends on the volume of CSF sampled and the diligence of microscopic evaluations[57,58]; large volumes (5–10 mL) of centrifuged CSF and ≥30 minutes of microscopic inspection yield better results. Growth of *M. tuberculosis* from CSF occurred in 155 of 374 (41%) children with TB meningitis reported, and yields as high as 70% have been reported when up to 10 mL of CSF is sampled.[1,46–49,51] Gastric aspirate or sputum AFB smear and culture can increase the probability of diagnosis in children. Nucleic acid amplification (NAA) tests, such as polymerase chain reaction (PCR), are commercially available to detect mycobacterial DNA in CSF. A meta-analysis of the accuracy of NAA for diagnosing tuberculous meningitis revealed a sensitivity of 56% (negative predictive value, 44%) and a specificity of 98% (positive predictive value, 35.1%) among commercially available assays.[58] The PCR test can remain positive for several weeks after treatment is initiated.

Treponema pallidum

Epidemiology.

Chronic syphilitic meningitis is rare and occurs in <1% of persons with syphilis; the incidence of meningitis is greatest in the first 2 years after *T. pallidum* infection.[2] Incidence rates of syphilis have increased in the US in recent years, primarily among men who have sex with men.[59] Although neurosyphilis rarely manifests as chronic meningitis, partially treated neurosyphilis can imitate chronic meningitis.

Pathogenesis.

Congenital syphilis usually occurs by transplacental transmission of *T. pallidum* into the fetal circulation.[60] Postnatally acquired syphilis develops by penetration by *T. pallidum* through mucous membranes or abraded skin after direct contact with ulcerative lesions of infected people. The organism disseminates lymphohematogenously and can invade the CNS.

Clinical Manifestations.

In children, syphilis usually is congenitally acquired. Most infants do not have symptoms at birth, although those with syphilitic meningitis are more likely to have symptoms than those without meningitis. Common clinical features of congenital infection include ≥1 of the following: hepatosplenomegaly, mucocutaneous lesions, lymphadenopathy, and osteochondritis.[61] About 50% of infants with symptoms of congenital syphilis and 10% of asymptomatically infected infants have CSF abnormalities: a reactive Venereal Disease Research Laboratory (VDRL) test, elevated white blood cell (WBC) count, and/or elevated protein level. Despite CNS infection and abnormal CSF, neurologic signs or symptoms usually are not detectable.[62] Without treatment, congenitally infected infants can develop acute leptomeningitis between 3 and 6 months of age with ≥1 of the following signs: stiff neck, vomiting, bulging fontanel, or hydrocephalus.[61] If untreated, chronic meningovascular syphilis with progressive hydrocephalus, cranial nerve palsies, and intellectual deterioration develops by 12 months of age.

About one third of patients with the early stage of postnatally acquired syphilis have CNS involvement, which may or may not lead to acute meningovascular neurosyphilis. If untreated, one half of those with CNS infection develop symptomatic or asymptomatic late neurosyphilis. Features of symptomatic late neurosyphilis include dementia, tabes dorsalis, meningovascular disease, seizures, and optic atrophy.

Laboratory Findings and Diagnosis.

The diagnosis of syphilitic meningitis can be difficult. A serum fluorescent treponemal antibody, absorbed (FTA-ABS) test is positive in >95% of patients. If the serum FTA-ABS test result is negative, the probability of syphilitic meningitis is very low (except in patients with poorly controlled HIV infection, who may fail to produce antibodies).

Useful tests for CSF samples include specific treponemal immunoglobulin M antibodies, VDRL test, and FTA-ABS.[63] The specificity of the VDRL test on CSF is high, but sensitivity is low (30%–70%). A nonreactive result does not exclude the diagnosis. False-positive reaction can be due to blood contamination or high CSF protein. In contrast, a negative result of FTA-ABS test on CSF rules out neurosyphilis, but a positive test does not confirm the diagnosis because false-positive results can occur as a result of CSF contamination with blood or small amounts of antibodies from the serum. The best indicator of CNS infection in neonates is an abnormal physical examination, anemia, thrombocytopenia, CSF abnormalities, and abnormal bone radiographs. Detection of *T. pallidum* DNA in the blood or CSF by PCR is highly predictive of neurosyphilis.[62] PCR testing is sensitive for diagnosis of acute neurosyphilis but is less useful in chronic cases.[64] CSF chemokine CXCL13 level is elevated in neurosyphilis but can also be elevated in other conditions, so its diagnostic value remains to be determined.[65]

Brucella Species

Epidemiology.

Brucellosis is a zoonotic disease, associated particularly with sheep, goats, swine, and cattle. Humans become infected by direct contact with infected animals or by ingestion of unpasteurized milk products. There does not appear to be an increased risk for patients with underlying diseases.[66] Brucellosis is uncommon in the US, with about 100 cases annually, and less than 10% occurring in children.[67] Brucellosis is a common disease worldwide. Thus a history of travel and consumption of unpasteurized dairy products is important, especially travel in the Mediterranean region, India, or Latin America. Meningitis occurs in fewer than 5% of patients with brucellosis and is the first manifestation of the disease in about 1%. The incubation period varies from <1 week to several months, with an average of 3 to 4 weeks.

Pathogenesis.

Brucella are facultative intracellular pathogens that can survive and multiply within phagocytes and other cells. It is postulated that infected leukocytes carry organisms into the CNS.[68] Another hypothesis is that bacteria enter the CNS through direct endothelial cell invasion.

Clinical Manifestations.

Meningitis is the most common presentation of neurobrucellosis. Symptoms are nonspecific and include fever, headache, myalgia, sweating, vomiting, and meningeal irritation.[3,69,70] CSF findings include lymphocytic pleocytosis with a low to normal glucose concentration and high protein concentration. Systemic manifestations of brucellosis may be present. If treated, the prognosis usually is good; however, cases with serious neurologic sequelae are reported.[69]

Laboratory Findings and Diagnosis.

Because neurobrucellosis has nonspecific symptoms, it is important to obtain a careful history regarding travel, diet, and animal exposures. CSF lymphocytic pleocytosis with low to normal glucose and elevated protein concentrations is typical. The CSF Gram stain usually is negative. CSF culture is positive in <25% of cases; cultures of blood and, especially, bone marrow increase the diagnostic yield. The laboratory should be advised to maintain the cultures for at least 4 weeks. The diagnosis can be confirmed by detection of specific *Brucella* antibodies in the CSF or serum by agglutination or enzyme immunoassay (EIA) and Western blot.[71,72] PCR detection of *Brucella* DNA in the CSF or serum is a promising tool.[73–75]

Borrelia burgdorferi

Epidemiology.

Borrelia burgdorferi should be considered in endemic areas, which includes the northeast, upper Midwest, and northern Pacific coast of the US. Approximately 2% of children with Lyme disease develop clinical evidence of meningitis.[76] Chronic meningitis with serious neurologic sequelae is rare.[4]

Pathogenesis.

The spirochete enters the host from a bite of an infected tick: *Ixodes scapularis* in the northeast and upper Midwest of the US or the *Ixodes pacificus* in the West. *Borrelia* multiplies locally in the skin at the site of the tick bite. Local inflammation typically results in erythema migrans. In days to weeks, the spirochete can spread lymphohematogenously to other sites, including the CNS.

Clinical Manifestations.

Meningitis usually manifests during the early disseminated phase of disease with acute onset of symptoms similar to viral meningitis: fever, headache, stiff neck, and malaise. However, clinical symptoms with Lyme meningitis usually are prolonged (>7 days) compared with viral meningitis.[77–79] In addition, about one half of patients develop cranial neuropathies, with facial palsy being the most common. The prognosis usually is very good with therapy. If untreated, symptoms may persist for months.

Laboratory Findings and Diagnosis.

Residence in or travel to an endemic area and a history of untreated erythema migrans are important clues to the diagnosis. The CSF typically shows a modest monocytic and lymphocytic pleocytosis with modestly elevated protein concentration. In the absence of a history of erythema migrans, the features of prolonged headache, cranial neuropathy, and predominance of CSF mononuclear cells can help distinguish Lyme meningitis from other forms of aseptic meningitis.[77–79] Spirochetes can only rarely be isolated from CSF using a specific culture medium.[80–82] Intrathecal antibodies specific to *B. burgdorferi* can be measured by EIA, although the sensitivity and specificity of the test is uncertain.[81,82] Simultaneous serum antibodies should be obtained so that the CSF/serum antibody ratio can be determined.[80,82] An elevated CSF/serum antibody ratio might reflect past CNS infection but, in conjunction with a CSF pleocytosis and elevated protein, can be used to support the diagnosis of active infection. DNA PCR detection of *B. burgdorferi* from the CSF has good specificity, but poor sensitivity—ranging from 20% to 50% in acute cases to 0% to 25% in chronic cases.[82,83] Because of limited studies, the advantage of immunoassays over PCR for diagnosing Lyme meningitis has not been demonstrated conclusively. If the result for the immunoassay is negative and there is a high suspicion of Lyme neuroborreliosis, PCR testing may be considered. CSF levels of the chemokine CXCL13 are elevated in neuroborreliosis and decline with treatment. However, other conditions can cause elevated CSF CXCL13, and its diagnostic value for Lyme neuroborreliosis is uncertain.[84]

Other Bacteria

Leptospirosis is a rare cause of chronic meningitis because the clinical signs and symptoms of meningitis generally disappear within 7 to 21 days.[9] Other rare bacterial causes include *Nocardia*,[5] *Actinomyces*,[6] nontuberculous mycobacterdia[7,8] and *Tropheryma whipplei*.[10] Both *Mycoplasma hominis* and *Ureoplasma urealyticum* can cause chronic meningitis in preterm infants associated with development of hydrocephalus.[11]

Cryptococcus Species

Epidemiology.

Cryptococcus neoformans is a yeast-like fungus with worldwide distribution and is probably the most common cause of fungal meningitis in immunocompromised adult patients. Although *Cryptococcus* can infect normal hosts, it more commonly develops in patients with risk factors for primary impaired cellular immunity, high-dose corticosteroid treatment, leukemia, lymphoma, or HIV infection. Cryptococcal meningitis develops in up to 10% of adults with AIDS; it is the most common life-threatening fungal infection in patients with poorly controlled HIV infection, and in 40% of those affected, it is the first AIDS-defining opportunistic infection.[85] However, cryptococcal meningitis is relatively rare in children. Abadi and colleagues retrospectively compiled 30 cases of *C. neoformans* infections in HIV-infected children from 1985 to 1996 and estimated a 1% 10-year point prevalence of cryptococcosis among children with AIDS.[86] *Cryptococcus gattii* historically was found more often in tropical and subtropical geographic regions, but now is reported in temperate areas, mostly on the west coast of California and British Columbia.[87] *C. gattii* meningitis is associated with progressive CNS disease in immunocompetent patients, suggesting that genotypic or phenotypic differences of the fungus, or both, may explain its virulence in immunocompetent hosts.[87]

Pathogenesis.

C. neoformans is found in bird droppings and soil, and *C. gattii* is found in certain trees and soils. Humans become infected by inhaling airborne fungi into the lungs, where organisms can spread lymphohematogenously to the meninges.

Clinical Manifestations.

The most common presenting signs and symptoms are insidious onset of headache, fever, vomiting, nuchal rigidity, changes in mental status, and seizures.[85,86] Focal neurologic signs are not uncommon. The clinical presentation can be very similar to tuberculous meningitis. However, some patients can be completely asymptomatic.[88]

Laboratory Findings and Diagnosis.

CSF typically shows lymphocytic pleocytosis and low glucose concentration; however, infected patients with AIDS can have normal CSF findings.[85] Nevertheless, most patients have confirmatory findings from CSF India ink or calcofluor white fluorescent stains, CSF or serum cryptococcal antigen, and CSF fungal culture. Fungal cultures of the blood, urine, and sputum (if available) should be obtained, even in patients without clinical manifestations of specific organ involvement. Repeated large volumes (5–10 mL) of CSF sampling may be needed to confirm the diagnosis. The possibility of capsule-deficient *Cryptococcus* should be considered in the rare event that the diagnosis is suspected strongly but the staining and antigen detection tests are negative. In such cases, the diagnosis can be established by indirect immunofluorescence staining or reformation of the capsule by inoculation into mice, although the latter is not available readily.[89]

Histoplasma Species

Epidemiology.

Histoplasma capsulatum is a dimorphic fungus found in soil and is endemic in the Mississippi, Ohio, and Missouri River valley regions of the US. CNS infection is rare and usually occurs in immunocompromised or malnourished individuals or infants. Neurologic involvement is reported in 8% to 18% of cases of disseminated disease,[17] but an incidence of 55% has been found in AIDS patients with disseminated histoplasmosis.

Pathogenesis.

Humans become infected by inhaling spores into the lungs, which then spread lymphohematogenously to the meninges or brain.

Clinical Manifestations.

In a report of 18 cases and review of 86 cases from the literature, chronic meningitis was the most common form of CNS *Histoplasma* infection, with about 40% of patients coming to medical attention with accompanying disseminated histoplasmosis and 25% with isolated chronic meningitis.[17] Clinical symptoms are nonspecific among chronic meningitis cases and include headache (24%), depressed level of consciousness (29%), confusion (22%), and cranial neuropathy (19%). Personality changes and seizures occur in 10% to 15% of patients. Fever typically is present. The onset of symptoms is at least 2 months before diagnosis in more than 70% of cases.

Laboratory Findings and Diagnosis.

CSF reveals an elevated protein concentration, modestly low glucose concentration, and 50 to 500 WBCs/mm^3 (predominantly mononuclear cells).[17] CSF culture for *Histoplasma* is positive in 30% to 50% of cases. Culturing a large volume (>10 mL) of CSF is recommended for optimal yield.[90] Blood culture is positive in about 50% of cases. *Histoplasma* antigen can be assayed in blood, urine, and CSF. In earlier reports, the sensitivity of antigen detection in chronic meningitis was 38% in blood, 71% in urine, and 38% in CSF. However, a new assay with improved sensitivity is available commercially, but performance in CSF samples has not been evaluated sufficiently. The antigen test can cross-react in cases of blastomycosis. CSF and serum antibody tests are approximately 90% sensitive but can reflect past infection. In addition, the antibody response can be impaired in immunosuppressed individuals, and the test can have false-positive results because of cross-reactions caused by infection with other fungi, including *C. neoformans*. Current recommendations to evaluate for CNS histoplasmosis are to perform multiple tests, including (1) fungal culture, antigen, and antibody tests on CSF; (2) fungal culture, antigen, and antibody tests on blood; and (3) antigen test on urine.[91] CSF specimens should be obtained repeatedly if there is no diagnosis and suspicion for histoplasmosis remains. Chest radiographs may provide a clue to the diagnosis; one half of cases have abnormalities consistent with histoplasmosis.[90]

Coccidioides Species

Epidemiology.

Coccidioides species are dimorphic fungi found in the soil of southwestern US, northern Mexico, Central America, Venezuela, Argentina, and Paraguay. Primary infection develops from the inhalation of airborne spores and occurs most frequently in the summer and fall. The incidence of coccidioidomycosis appears to increase when rainy summers are followed by dry winters and windstorms.[91] Although respiratory infection with *Coccidioides* is common, disseminated disease develops in only 1% of persons. Approximately one third of patients with disseminated disease develop meningitis. Those at increased risk for disseminated disease and meningitis include immunosuppressed hosts, African American and Filipino people, pregnant women, neonates, and elderly people.[92]

Pathogenesis.

Airborne spores are inhaled into the lungs, where organisms then can spread lymphohematogenously to the meninges or brain.

Clinical Manifestations.

Primary respiratory infection often is asymptomatic, but fever, malaise, cough, myalgia, headache, and chest pain can occur. The most common presenting symptoms of meningitis in adults include headache (75%), nausea and vomiting (52%), and fever (50%). Meningismus and focal neurologic symptoms occur in one third and one fourth of patients, respectively.[18]

Laboratory Findings and Diagnosis.

A history of travel or residence in endemic areas provides an important clue to the diagnosis. Cranial CT or MRI is abnormal in more that one half of cases, with basilar enhancement, hydrocephalus, or infarctions the most common findings.[18] Visualization of *Coccidioides immitis* in CSF samples is rare, and although the organism is not fastidious in growth requirements, only about one third of patients with meningitis have a positive CSF culture. Sampling of large volumes of CSF, followed by sterile filtration and culture of the filter, increases the yield. Detection of antibodies to *Coccidioides* by EIA has a sensitivity of 93% on serum and 75% on CSF specimens.[18] Diagnosis by real-time PCR analysis of CSF may be promising.[93]

Other Fungi

The usual course of *Candida albicans* meningitis is acute. Chronic meningitis is an uncommon manifestation of disseminated candidiasis that can be seen in premature infants and children with congenital immunodeficiencies. CNS *Candida* infection also can occur in children with a ventriculoperitoneal shunt. Chronic meningitis due to *Blastomyces dermatitidis* is uncommon but should be considered in the immunocompetent host from an endemic area (i.e., the Mississippi and Ohio River valley regions and regions along the Great Lakes and the St. Lawrence River of the US). Other fungi, such as *Aspergillus, Sporothrix, Cladosporium,* and *Allescheria* spp., and agents of mucormycosis and phaeohyphomycosis are rare causes of chronic meningitis. Disseminated aspergillosis often involves the CNS, but usually as a focal brain lesion, and not as isolated chronic meningitis. Fungal meningitis can occur rarely from CNS-related procedures, as recently reported in a large multistate outbreak of polymicrobial fungal CNS infections due to contaminated epidural or paraspinal administration of compounded methylprednisolone formulations.[94]

Parasites

Protozoa and parasites can cause chronic meningitis, including *Toxoplasma,*[26] *Taenia,*[27] and rarely *Acanthamoeba,*[28] *Balamuthia,*[29] *Baylisascaris,*[31] and *Angiostrongylus* spp.[30] Reactivation of *Toxoplasma gondii* is a rare cause of CNS infection in immunosuppressed children and usually causes focal brain lesions rather than meningitis. *Taenia* tapeworms endemic to Latin America, Asia, and East Africa can form cysts in the brain (neurocysticercosis) that most commonly result in acute onset of afebrile seizures; neurocysticercosis rarely presents as chronic meningitis.

Viruses

HIV is probably the most common viral cause of chronic meningitis,[12] but patients with poorly controlled HIV infection also can develop chronic cytomegalovirus (CMV) meningitis. In patients with agammaglobulinemia, enteroviruses can cause persistent meningitis.[14] Another rare viral cause of chronic meningitis is lymphocytic choriomeningitis virus.[13] Diagnosis based on viral isolation from the CSF or demonstration of specific antibody responses (in blood or CSF) can require 4 to 6 weeks and is insensitive. PCR assays offer rapid detection (within hours if necessary) for many viruses (e.g., enteroviruses, CMV) with excellent sensitivity and specificity. In chronic meningitis viral replication can be low; PCR especially is valuable.

Evaluation

Before testing for the myriad infectious causes of chronic meningitis (see Table 41.1), noninfectious and parameningeal conditions should be considered (see Boxes 41.1 and 41.2). In addition, cases of recurrent meningitis (i.e., repeated episodes of acute meningitis separated by symptom-free periods) should be distinguished from chronic meningitis (see Chapter 42). Fig. 41.1 is an algorithm to guide differential diagnosis.

FIGURE 41.1 Algorithm for evaluation of patients with signs and symptoms of chronic meningitis.

History

Although the exact cause of chronic meningitis may not be found in up to one third of cases,[43,44] close attention to details can provide important clues to the diagnosis, or at least help narrow the differential diagnosis. A history of environmental exposure (e.g., travel, drugs, unusual foods, animals, insects) or exposure to persons infected with pathogens spread by person-to-person contact (e.g., tuberculosis, syphilis, HIV) should be sought (Table 41.2). The travel history should be thorough and include travel or residence in both domestic and international regions. Concomitant symptoms, such as rash or chronic cough, can assist in determining the etiology. Although in most cases signs and symptoms of illness develop within a short time after the exposure (such as in brucellosis, Lyme disease, and blastomycosis), a long incubation period (such as for cysticercosis) or reactivation of a dormant focus several years after exposure (such as in the source adult with tuberculosis, in histoplasmosis, and toxoplasmosis) can occur.

TABLE 41.2

Agent Causing Chronic Meningitis and Likely Exposure History in Patient

Agent	Exposure History
Brucella spp.	Ingestion of unpasteurized dairy products or animal contact, especially in the Mediterranean, India, or Latin America
Leptospira spp.	Occupational (farmer) or recreational (camper, swimmer) exposure to urine of wild and domestic mammals during summer and fall
Borrelia burgdorferi	T/R[a] in northeast United States, Wisconsin, Minnesota, California, and Oregon, especially during late summer and early fall, or in Europe, China, Japan, and Australia, with consequent tick exposure
Blastomyces spp.	T/R in Ohio and Mississippi River valleys or North Carolina
Histoplasma sp.	T/R as for *Blastomyces*, plus Appalachian mountains and Virginia
Coccidioides sp.	T/R in southeastern United States, Mexico, Central America, Venezuela, Argentina, or Paraguay
Sporothrix sp.	T/R in tropical and subtropical Americas, or a prick from a rose thorn
Cysticercosis	T/R in Latin America, Southeast Asia, Africa, eastern Europe, and southwestern United States
Angiostrongylus sp.	T/R in Hawaii, Australia, Southeast Asia, or Philippines
Baylisascaris sp.	Exposure to raccoon feces

[a] T/R, travel or residence.

A careful history also can reveal predisposing conditions that increase the risk for opportunistic infections (Table 41.3). For example, prematurity, prolonged use of corticosteroid therapy, cancer, HIV infection, intravenous drug abuse, or use of indwelling catheters facilitates invasion and dissemination of *Candida* spp. Direct extension of *Aspergillus* spp. infection from an adjacent sinus, ear, or orbit or after head trauma or surgery can lead to infection of the CNS.

[c] In AIDS patients.

AIDS, acquired immunodeficiency syndrome; CMV, cytomegalovirus; HIV, human immunodeficiency virus

Skin.

The skin examination can reveal a typical lesion, such as the erythema migrans of Lyme disease, or provide a source for culture or biopsy to identify an etiology. Erythema nodosum is seen in some diseases, and nonerythematous nodules can be found in patients with systemic candidiasis, blastomycosis, and nocardiosis. Although uncommon, the umbilicated nodules of cryptococcal infection in HIV-infected patients and the characteristic palmar lesions of secondary syphilis can guide investigations.

Lungs.

The lungs are the portal of entry for many of the pathogens that cause chronic meningitis, including *Blastomyces, Cryptococcus, Coccidioides, Histoplasma,* and *M. tuberculosis*. Careful physical examination and selective laboratory evaluations (chest radiography, microscopy, sputum culture, and, occasionally, lung biopsy) can be useful.

Eye.

An examination by an ophthalmologist can sometimes identify important ocular lesions suggestive of an etiology. Findings of endophthalmitis can support the diagnosis of infection with

Candida, *Cryptococcus*, and rarer infections. Chorioretinitis can be indicative of CMV, histoplasmosis, or toxoplasmosis. Uveitis might suggest a possible noninfectious etiology, such as systemic lupus erythematosus (SLE). If mental status changes or papilledema are present, cranial CT should precede performance of the lumbar puncture.

Neurologic Examination.

The neurologic examination is of limited use in identifying a specific etiology, because a variety of neurologic abnormalities can be seen with most causes of chronic meningitis. Cranial neuropathy is more commonly seen with syphilis, tuberculosis, and Lyme disease. Peripheral neuropathy and chronic meningitis may indicate Lyme disease, CMV infection, or SLE.

Liver.

Hepatomegaly, not a common finding in patients with chronic meningitis, should direct the diagnosis toward a relatively few associated pathogens (see Table 41.4).

Imaging Studies

CT or MRI with contrast material should be performed before lumbar puncture to exclude space-occupying lesions, hydrocephalus, or increased intracranial pressure. Imaging also can help to identify a parameningeal infectious site, meningeal inflammation, focal brain lesions, or cerebral infarction. Because the lungs often are the primary site of infection for many organisms that cause chronic meningitis, chest radiograph is obtained routinely.

Cerebrospinal Fluid Analysis

Most infectious causes of chronic meningitis elicit similar CSF abnormalities (i.e., pleocytosis <500 WBCs/mm^3, with lymphocyte predominance, low or normal glucose concentration, and elevated protein concentration), but CSF findings can help to direct the differential diagnosis (Table 41.5). An infectious cause other than early *M. tuberculosis* is rare when CSF has <50 WBCs/mm^3; in such cases, noninfectious causes should be considered.

TABLE 41.5

Predominant Leukocyte Found in Cerebrospinal Fluid for Various Causes of Chronic Meningitis

	Predominant Leukocytes in CSF		
Causative Agent	**Lymphocytes**	**Neutrophils**	**Eosinophils**
Bacteria	*Mycobacterium tuberculosis*	*Nocardia*	*Mycobacterium tuberculosis*
	Treponema pallidum	*Actinomyces*	*Treponema pallidum*
	Borrelia	*Brucella*	
	Brucella	*Leptospira*	
Fungi	All	All	*Coccidioides*
Parasite	*Taenia*	*Entamoeba histolytica*	*Angiostrongylus*
	Toxoplasma		*Taenia solium*
			Baylisascaris
Viruses	LCMV	Mumps	
	CMV	CMV[c]	
Other	Parameningeal focus[a]	Suppurative parameningeal focus[a]	Hodgkin disease
	Sarcoidosis[b]	Systemic lupus erythematosus	Chemical meningitis
	Chronic idiopathic meningitis	Chemical meningitis	Drug hypersensitivity
	Malignant process	Drug hypersensitivity	
	Behçet disease	NOMID/CINCA	

[a] See Box 41.2.

[b] See Box 41.1.

[c] In AIDS patients.

AIDS, acquired immunodeficiency syndrome; CMV, cytomegalovirus; LCMV, lymphocytic choriomeningitis virus; NOMID/CINCA, neonatal-onset multisystem inflammatory disease/chronic infantile neurologic cutaneous articular syndrome.

CSF pleocytosis with predominance of neutrophils is uncommon in chronic meningitis but can be seen in infection due to *Actinomyces, Nocardia, Aspergillus,* or *Candida* spp. and early in tuberculous meningitis. A suppurative parameningeal focus, such as brain abscess, subdural or epidural empyema, cranial osteomyelitis, mastoiditis, or sinusitis, can cause sympathetic inflammation in the CSF, mild pleocytosis, and mild elevation of protein, typically without hypoglycorrhachia. Noninfectious causes of neutrophilic pleocytosis in CSF include SLE, exogenous chemicals (e.g., radiographic contrast material, chemotherapeutic agents, povidone iodine), and drugs (i.e., isoniazid, ibuprofen, or sulfa drugs).

Eosinophilic pleocytosis in chronic meningitis occurs rarely, and possible etiology includes parasites, such as *Angiostrongylus cantonensis, Taenia solium,* and *Baylisascaris procyonis* (ascarid of raccoons). Neurosyphilis, tuberculous meningitis, and coccidioidal meningitis rarely can cause mild CSF eosinophilia (<10% of WBCs). Noninfectious processes, such as Hodgkin disease, chemical meningitis, drug hypersensitivity, and complications of ventriculoperitoneal shunts, also should be considered in the differential diagnosis of CSF eosinophilia.

Stains for bacteria, fungi, and acid-fast organisms should be performed. Special staining (using monoclonal antibodies) of lymphocytes in CSF should be considered if leukemia or lymphoma is suspected. Culture of a CSF sample is important and should include appropriate techniques for isolation of aerobic, facultative anaerobic, and fastidious bacteria (e.g., increased CO_2 to enhance growth *of Actinomyces, Nocardia,* and *Brucella* spp.); fungi; and mycobacteria. Cultures should be incubated for an extended time because growth of some bacteria and fungi is slow.

CSF and serum for cryptococcal antigen should be performed in most instances. When indicated, testing for CSF antibodies to agents, such as *Treponema pallidum, Borrelia burgdorferi, Histoplasma capsulatum, Coccidioides immitis, Sporothrix schenckii, Toxoplasma gondii,* and *Taenia* spp., is performed with concurrent serum specimen testing. (1-3)-β-D-glucan testing of CSF may become useful for suspected fungal meningitis.[95,96] Measurement of antigen in CSF or blood and PCR testing are available for some pathogens (Table 41.6). Lumbar puncture may need to be repeated for cultures and additional studies and to follow the course of meningeal inflammation.

TABLE 41.6

Commercially Available Diagnostic Tests for Causative Agents of Chronic Meningitis[a]

	CSF					Blood	
Agent	Stain	Culture	Antigen	Antibody	PCR	Ab	Ag
Mycobacterium tuberculosis	+	++			++		

Treponema pallidum	+/–			+++	++	+++	
Brucella	+/–	+		++		++	
Borrelia burgdorferi	+/–	+/–		++	+	+++	
Nocardia	+/–	++					
Actinomyces	+/–	++					
Leptospira		+/–				++	
Mycoplasma		++			+++		
Ureaplasma		++			+++		
Blastomyces	+/–	+/–		+		+	
Histoplasma	+/–	+/–	++	+		+	++
Coccidioides	+/–	+	++	+		+	++
Cryptococcus	++	+	+++			++	++
Candida	++	+++	+				
Aspergillus	+/–	+			++		++
Sporothrix	+/–	+		+	++	+	
Toxoplasma	+/–	+/–		++	+++	++	
Angiostrongylus	+		++				
Taenia				++		+++	
Viruses		+		+	+++	+	

[a] +++ Test of choice; ++ modestly useful; + occasionally useful; +/− rarely useful.

Ab, antibody; Ag, antigen; CSF, cerebrospinal fluid; PCR, polymerase chain reaction.

Additional Evaluations

Many patients with chronic meningitis also have disseminated disease; therefore, fungal and mycobacterial blood and urine cultures should be considered. With an appropriate exposure history, serologic tests for some pathogens (see Table 41.6) can be diagnostic. Because immunodeficiency greatly modifies the differential diagnosis, HIV testing should be performed for all patients with chronic meningitis. If immune suppression is considered likely, PCR assays may be more reliable than antibody testing. A Mantoux tuberculin skin test or, in children 5 years or older, an interferon γ release assay (IGRA) on blood is indicated to evaluate for tuberculosis. Repeat testing may be helpful if tuberculosis remains a concern. Brain biopsy should be considered when the diagnosis remains elusive and radiographic imaging identifies a focal lesion or meningeal enhancement.[97]

Empiric Therapy

When the initial evaluation of the patient identifies the cause of chronic meningitis, specific therapy should be instituted. When choosing the antimicrobial agent or agents, the drug's ability to penetrate the blood-brain or CSF barrier to achieve consistent and adequate drug levels is of paramount importance. Chapters on specific pathogens contain specific recommendations.

After the initial evaluation, the cause of chronic meningitis remains unknown in many patients. In these situations, decisions regarding use of empiric treatment and preferred antimicrobial agents are controversial. Because tuberculous meningitis is probably the most common cause of chronic meningitis, an empiric trial with antituberculous drugs is favored by many clinicians. However, such an approach was not found to be beneficial in one study from the Mayo Clinic.[98] If empiric antituberculous therapy is initiated, further studies should be done in patients who are seriously ill or who deteriorate rapidly. Corticosteroid therapy should only be added if the patient continues to deteriorate while receiving antituberculous therapy or if fungal meningitis is reasonably excluded. Several adults with idiopathic chronic meningitis in the Mayo Clinic study were treated with empiric corticosteroid and had a favorable response.[98] The mean length of symptoms before starting corticosteroids was 17 months. Corticosteroid therapy should be considered cautiously because of the potential catastrophic outcome when given to patients with unrecognized and untreated tuberculous or fungal meningitis. If fungal meningitis is a possibility, empiric antifungal treatment should be considered, recognizing the potential adverse drug effects, and that response to therapy may be difficult to determine because patients with fungal meningitis often respond slowly to treatment. Choice of antifungal agent should be made on the basis of activity against the suspected organism and CSF penetration.

In previously healthy patients who have had symptoms of meningitis for several weeks and who are not seriously ill, it is reasonable to investigate the cause of meningitis without initiating treatment. If the cause cannot be found and the patient is not improving, empiric therapy is considered. If antituberculous medications are initiated and the patient does not improve within a few weeks, antifungal therapy should be considered.

Recurrent Meningitis

Robyn A. Livingston, Christopher J. Harrison

Recurrent meningitis typically is defined as two or more separate episodes of meningitis weeks to months apart with full recovery between events. This is in contrast to recrudescence or relapse of meningitis, which represents persistence of the original infection due to treatment failure.[1] Recurrent meningitis is relatively uncommon, and its etiology often is difficult to determine. When the cause is detected, most cases are bacterial in origin, although recurrent episodes can be characterized by negative cerebrospinal fluid (CSF) cultures, and rarely a virus such as herpes simplex virus (HSV) can be causative.

Etiologic Agents

The pathogen in more than 50% of patients with recurrent bacterial meningitis is *Streptococcus pneumoniae*, most often in association with an underlying anatomic abnormality or immunodeficiency. *Neisseria meningitidis* is the second most common bacterial pathogen, accounting for approximately 25% of cases of recurrent bacterial meningitis,[1] most often associated with complement deficiency. Recurrent meningitis due to *Haemophilus influenzae* type b (Hib) has been reported rarely since the introduction of conjugate Hib vaccine. *Staphylococcus aureus* and gram-negative bacilli such as *Escherichia coli* can be associated with recurrent meningitis; the recurrent isolation of any of these organisms suggests a communication between the subarachnoid space and the paranasal sinuses, skin (such as a dermal sinus), or intestine if gram-negative organisms are isolated (such as posterior neurenteric fistula or anterior meningomyelocele). Other bacteria, such as oral streptococci, *Proteus* spp., enterococci, *Klebsiella* spp., and group B *Streptococcus* have been sporadically reported to cause recurrent meningitis. In cases in which bacteria cannot be detected, the differential diagnosis of recurrent aseptic meningitis should be considered (Box 42.1).[2–15]

Box 42.1

Conditions Associated With Recurrent Aseptic Meningitis

Mollaret syndrome[2]

Familial Mediterranean fever (FMF)[3]

Intracranial or intraspinal cyst[4]

Dermoid or epidermoid tumor[5]

Behçet disease[6]

Sarcoidosis[7]

Systemic lupus erythematosus[8]

Intracranial tumor[9]

Drug-induced (e.g., penicillins, cephalosporins, trimethoprim-sulfamethoxazole, nonsteroidal anti-inflammatory drugs, immune globulin intravenous, OKT3)[10,11]

Herpes simplex virus type 1 or 2 infection[12]

Enterovirus infection[13]

Migraine syndrome[14]

Vogt-Koyanagi-Harada syndrome[15]

Epidemiology

Recurrent episodes of meningitis are rare, and the prevalence for each of the predisposing causes varies. A 1999 review of 463 cases of bacterial meningitis in children identified 6 patients with confirmed recurrent episodes, representing 1.3% of bacterial meningitis cases.[16] The most common predisposing condition is a communication between the subarachnoid space and the base of the skull (CSF leak or fistula) resulting from head trauma, surgery, or a congenital defect; immunologic defects are less common. CSF rhinorrhea or otorrhea occurs after approximately 1% to 2% of all head injuries, but either condition is more frequent in selected presentations (i.e., 11% of basilar skull fractures[17] and 25% of fractures involving the paranasal sinuses[18]). Most CSF leaks resolve spontaneously within a few days. Persistent CSF leaks are associated with an increased risk for meningitis.[19]

The risk for development of meningitis at a particular time after injury varies. About one fifth of cases of posttraumatic meningitis occur within 1 to 2 weeks after head trauma,[20] one third within the first month, and half within 6 months. However, almost 50% of patients have the first episode of meningitis ≥7 months after the traumatic event causing a CSF leak, and delay of as long as 34 years has been reported.[21] Procedures such as intracranial surgery, nasal and paranasal sinus surgery, and otologic surgery also can predispose to recurrent meningitis.[18] On average, postneurosurgical meningitis develops within 10 days of the procedure, with an incidence of 0.3% to 8.9%[22]; gram-negative bacteria frequently are isolated.

Various congenital defects in the bony structure of the skull contribute to the development of CSF fistulas and thus predispose to recurrent meningitis (Box 42.2). The incidence of recurrent meningitis in patients with a congenital defect is unknown but probably is low, although the defects themselves are not uncommon. For example, in children with idiopathic sensorineural hearing loss, computed tomography (CT) of the temporal bone revealed that 21% had an inner-ear malformation.[23] Mondini dysplasia (a developmental arrest at the seventh week of gestation characterized by hypoplasia of the cochlear labyrinth resulting in 1 to 1.5 turns instead of the normal 2.5 turns and occasionally associated with intrauterine CMV infection) is commonly cited as contributing to recurrent meningitis (Fig. 42.1).[24] Although deafness frequently is associated with Mondini dysplasia, it is unilateral and therefore often unrecognized. Additionally, trauma can precipitate a fistulous connection in milder defects and lead to meningitis. Epidermoid and dermoid cysts with dermal sinus tract are well-known causes of recurrent meningitis, with many cases coming to attention because of a new-onset neurologic deficit, infection, or both.[25] Lymphangiomatosis of the skull is a rare cause of CSF leak and recurrent meningitis.[26]

The incidence of recurrent bacterial or culture-negative meningitis after a parameningeal focus of infection (Box 42.3) or related to more distant foci (e.g., endocarditis) is unknown, but these entities should be considered in the differential diagnosis of recurrent meningitis. Vein of Galen malformations have also been implicated as a cause of recurrent meningitis.

Immunologic Defects

Several disorders of the immune system can predispose to recurrent meningitis, particularly meningitis caused by encapsulated bacteria. These include antibody immunodeficiencies (X-linked agammaglobulinemia, common variable immunodeficiency, immunoglobulin G [IgG] subclass deficiencies), HIV infection, splenic dysfunction (i.e., surgical splenectomy, congenital asplenia, sickle cell disease, or hemoglobinopathies), properdin deficiency, and complement deficiencies (see Chapters 101 to 103).

The frequency of a persistent complement deficiency in the general population is most likely <0.03%.[27] Deficiency of properdin (the molecule that stabilizes the C3bBb complex) and terminal components of complement are associated with recurrent meningococcal infection. Meningitis occurs in approximately 39% of patients with terminal complement deficiencies and 6% of those with properdin deficiency.[28] Recurrent bacterial meningitis (especially due to *N. meningitidis*) occurs in patients with deficiency of one of the terminal complement components (i.e., C5 to C9) and can be mild. In contrast recurrent meningococcal meningitis is rare in individuals with properdin deficiency because the initial infection usually is fatal.[29]

Bacterial infections are less frequent in C4 deficiency, presumably because affected individuals can compensate through the alternative pathway. In general, C5 deficiency is associated with a higher incidence of bacterial meningitis than deficiencies in more terminal components, probably because C5 promotes chemotaxis that localizes infection before invading the meninges. Almost 50% of individuals with C6 deficiency and 40% with C7 deficiency experience bacterial meningitis. Specific defects in the trimeric C8 molecule are associated with race. Deficiency of the C8-α and C8-γ subunits (the portion responsible for membranolytic function) is seen in black and Hispanic populations, whereas deficiency of the C8-β subunit (the portion responsible for attachment of C8 to C5b67) is seen in white populations. Most patients with C9 deficiency are healthy and rarely have meningococcal meningitis. Reported complement deficiencies in blacks involve terminal components almost exclusively.[27]

Persons with a complement deficiency have a 42% lifetime risk for any meningococcal infection compared with 0.0072% in the general population.[27] An estimated 10% to 15% of all patients with single or recurrent systemic infections due to *Neisseria* spp. have a complement deficiency.[27,30] The median age for the first episode of meningococcal infection in the general population is 3 years (peak age, 3 to 8 months), compared with 17 years in individuals with complement deficiency. In addition, recurrent meningococcal infection is rare in the general population, and relapsing infection is uncommon, with a rate of about 0.6%. In contrast, the recurrence rate in patients with complement deficiencies is high, approximately 45%, and the relapse rate is 10 times higher than in the general population, about 6%. The mortality rate for meningococcal infection with meningococcemia was estimated to be 25% in the general population compared with only 6.9% for all complement-deficient patients and 4.5% for those with terminal complement deficiencies.

Deficiency in some immunoglobulin subclasses (such as IgG2 and

IgG3) is associated rarely with recurrent meningitis, as are mutations in mannose-binding lectin (MBL).[31–33]

Pathogenesis

Trauma and Congenital Defects

Recurrent meningitis after head trauma only occurs if, in addition to fracture, there is a tear of the dura. Because the dura is bound more tightly to the base of the skull in children than in adults, a higher incidence of CSF leak occurs after head trauma in children. CSF leak is a portal of entry for bacteria comprising normal flora of the nasopharynx into the central nervous system (CNS). Fracture through the paranasal sinuses can manifest as an apparent CSF leak only transiently or not at all, with recurrent bacterial meningitis perhaps the only indication of the abnormal communication. Fracture of the temporal bone is the most common cause of CSF leak into the middle ear.[34] After fracture of the petrous bone, CSF can leak into the nasopharynx, but the expected rhinorrhea may not be detected externally. Meningitis or recurrence can occur years or even decades after the initial skull fracture occurred. Obtaining a detailed history for previous head trauma is crucial.[35]

Encephalocele is a rare cause of CSF leak that predisposes to recurrent meningitis. The probable etiology is a small congenital defect in the skull bone that allows cerebral tissue to protrude, but trauma, intracranial infections, tumor, or a surgical procedure can be the cause.

In patients with congenital abnormalities of the inner ear, several mechanisms contribute to the communication between the CSF and the middle-ear space.[36] First, the cochlear aqueduct (i.e., the perilymphatic duct), which normally connects the subarachnoid space with the inner ear, can be abnormally wide, allowing CSF to flow freely to the inner ear (a cochlear implant using a spacer can provide the same connection). Second, a Hyrtl fissure (an embryonic cleft connecting the posterior fossa and the middle ear), which usually is obliterated during normal ossification of the petrous bone, can remain patent. Third, there may be an abnormal communication between the internal acoustic canal (traversed by the eighth nerve) and the perilymph of the vestibule. CSF leakage from the vestibule to the middle ear occurs most commonly through the oval window. A hole in the stapes footplate with CSF leakage through the oval window due to increased vestibular perilymph pressure that displaces the stapes footplate has been described.[37,38]

In Pendred syndrome (congenital perceptive hearing loss with thyroid enlargement and abnormal perchlorate test result), a cochlear defect that resembles Mondini dysplasia predisposes to recurrent meningitis.[39] In Mondini dysplasia, the CSF leaks into the middle ear through a defective foramen ovale.[40] In Klippel-Feil syndrome (low hairline with short neck and limitation of neck movement), several anomalies can predispose to recurrent meningitis.[41] The most common are inner-ear abnormalities, including fistulas through the oval window, stapes footplate, or round window or along the facial nerve. Anomalies of vertebral bodies with neurenteric cyst or fistulas or a dermoid cyst, with or without dermal sinus tract, also have been described in children with Klippel-Feil syndrome and can serve as portals for entry of bacteria.

Occult CNS abnormalities should be suspected in any patient who has recurrent meningitis and does not have known predisposing CNS abnormalities or underlying immunologic defects. A dermal sinus tract ending intracranially (Fig. 42.2) or intraspinally (Fig. 42.3) in a dermoid cyst can permit entry of skin flora into the subarachnoid space.[42] Thus meningitis caused by skin organisms (i.e., *Staphylococcus* spp., gram-negative bacilli) should prompt a careful search for such a lesion. Other abnormalities, such as an enteric cyst contained within a meningocele,[43] continuous sequestration of bacteria on a CNS shunt or in paraventricular sites (i.e., brain abscess[44]), or a neurenteric fistula, can serve as the entry points. Rare cases of recurrent meningitis also have been reported secondary to migration of a ventriculoperitoneal shunt through the bowel wall into the gastrointestinal tract, or associated with procedures to dilate the rectum or esophagus or after spinal arthrodesis for scoliosis.[45,46]

Immunologic Defects

The pathogenesis of bacterial infections in patients with complement deficiencies is not understood fully. In individuals with complement deficiency, as in the general population, specific antibodies against pathogenic bacteria develop after exposure early in life, even without clinical infection. Complement defect, however, precludes full bactericidal activity of antibodies, and affected individuals experience a lifelong susceptibility to these pathogens. Although this process explains recurrent infections, it fails to explain adequately the unique susceptibility to *N. meningitidis* but not to other gram-negative bacteria, such as *H. influenzae* or *E. coli,* or other encapsulated bacteria, such as *S. pneumoniae,* in such people. Additional factors that influence the activation of the complement system (e.g., the presence of sialic acid on the bacterial surface) also may be important in the unique susceptibility of these patients and could explain the excessive occurrence of serogroup Y *N. meningitidis* infections in patients with complement deficiency compared with the general population (44% vs. 11%, respectively).[27] The lower rate of mortality may be the result of lower virulence of infecting organisms or more effective recruitment of other host defense mechanisms, such as the C3b complement pathway, or less disturbance of clotting systems or less activation of systemic cytokine release.

Drug-Induced Meningitis

Drug-induced recurrent meningitis has been reported in connection with several antibiotics (e.g., trimethoprim-sulfamethoxazole, penicillin, and cephalosporins), nonsteroidal anti-inflammatory drugs (e.g., ibuprofen, naproxen), cytotoxic drugs (e.g., azathioprine, cytosine arabinoside), OKT3 monoclonal antibody, and immune globulin intravenous (IGIV).[10,11,47] The likely pathogenesis of meningitis in these situations is either a direct chemical irritation by the drug or a hypersensitivity reaction. In ibuprofen-induced meningitis, immune complexes have been found in the CSF.[48] The onset of drug-induced meningitis varies from a few minutes to several months after drug intake. The onset of IGIV-induced meningitis generally is <24 hours after administration. The CSF findings typically resemble those of bacterial or aseptic meningitis, (hundreds to several thousand white blood cells per cubic millimeter, a polymorphonuclear predominant pleocytosis, normal-to-low glucose concentration, and modestly increased protein level).[10]

Mollaret Meningitis

Mollaret meningitis is characterized by recurrent episodes of aseptic meningitis lasting 3 to 5 days followed by spontaneous recovery.[2] Symptom-free periods vary from weeks to months, and the period of recurrences usually is 3 to 5 years, although longer durations have been reported. Symptoms include fever, headache, and meningismus, with occasional transient neurologic findings. CSF analysis reveals a polymorphonuclear pleocytosis up to several thousand cells per milliliter early in the course of illness followed by a lymphocytic predominance later. Early in the course of illness, large “endothelial” cells (Mollaret cells) with distinct nuclear shapes, often with deep nuclear clefts, are seen commonly in the CSF but can be absent. Further ultrastructural and immunohistochemical studies suggest that these cells are of monocyte-macrophage lineage.[49] The protein level is moderately increased, and glucose concentration is normal or slightly decreased.

Several etiologies have been postulated for Mollaret meningitis. Eosinophilia in a few patients has suggested a possible allergic or hypersensitivity mechanism. Elevated CSF cytokines levels may cause the symptoms. The occurrence of uveitis or transient facial paralysis suggests that Behçet disease or sarcoidosis may be related etiologically. The resemblance of Mollaret meningitis to familial Mediterranean fever (FMF), specifically the pattern of recurrent attacks and the response to colchicine, suggests the possibility that FMF is one possible cause.[3] Intracranial and intraspinal epidermoid cysts can produce chemical meningitis upon release of contents into the subarachnoid space.[4,50] However, since the development of polymerase chain reaction (PCR) technologies, recent studies have shown that the CSF of many patients with benign recurrent lymphocytic meningitis, including Mollaret meningitis, contain HSV DNA.[12] In most cases, HSV-2 DNA was detected, in the absence of cutaneous lesions, suggesting that recurrent lymphocytic meningitis may be a unique presentation of HSV-2 infection of the CNS.[51]

Clinical Manifestations

In most patients the signs and symptoms of recurrent meningitis are suggestive of classic acute bacterial meningitis, although the intensity may be milder, resembling aseptic meningitis. Physical examination otherwise is normal. History of trauma, congenital abnormalities, or recent surgery should prompt a detailed physical examination for a CSF leak, including a detailed examination for skull fracture or congenital bony malformations. Anosmia, hearing loss, otitis media with effusion, and hemotympanum are important clues to the potential presence of congenital or acquired CSF fistula or head trauma. CSF rhinorrhea or otorrhea can be intermittent and can cease when increasing pressure during an acute episode of meningitis occludes fistulas. Certain maneuvers, such as coughing, sneezing, Valsalva maneuver, or bending the head forward, may initiate or exacerbate CSF rhinorrhea. The craniospinal axis (especially the occipital, lumbosacral, and midline face) should be examined carefully for a dimple or bulge, tract, tuft of hair, nevus, or hemangioma. Some patients note recurring fluid discharges from sites of a mucosal or cutaneous lesion (Figs. 42.4 to 42.6). Examination of the nasal cavity may reveal granulation tissue or a meningocele at the site of the leak.

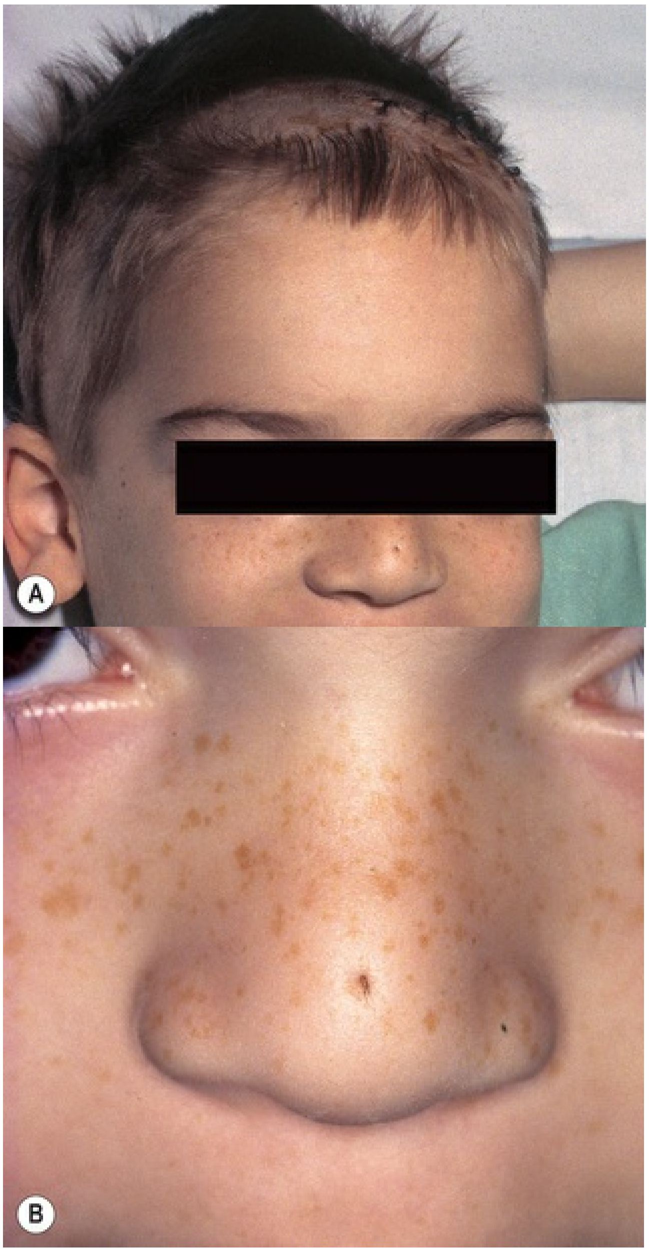

FIGURE 42.4 Dermoid cyst. A 6-year-old boy had a 3-week history of severe headache and then seizure, hemiparesis, and obtundation. *Enterobacter agglomerans* was isolated from a frontal lobe brain abscess and subarachnoid space. Postoperatively, a midline “comedone” was noted (A), which on closer inspection was a pit with a tuft of hair (B) overlying a dermoid cyst and tract to the subarachnoid space. The family recalled that the nose lesion had periodically discharged fluid over the child's lifetime. (Courtesy of E. N. Faerber and S. S. Long, St. Christopher's Hospital for Children, Philadelphia, PA.)

Note the tip of the spinal cord conus at L1–L2 level *(large arrow)* and enhancing soft tissue, bone, and bony canal in the sacral region *(small arrows)*. (Courtesy of J. H. Brien©.)

Diagnosis

If history of recurrent episodes of meningitis is obtained, special attention should be given to any history of head injuries, cranial surgery, multiple serious non-CNS bacterial infections, family history of recurrent infections, splenectomy, fluid leakage from ears or nostrils, and medication use. In addition, any child who experiences meningitis and has known deafness or a family history of anomalies of the ear should be evaluated for anatomic abnormalities, as should individuals whose deafness is discovered in association with meningitis after trauma. Evaluation of children with recurrent meningitis requires coordinated efforts, frequently between neuroradiology and neurosurgery. An algorithm has been proposed for diagnostic tests for children with recurrent meningitis of unknown origin.[16]

The results of tests performed on CSF from episodes of meningitis help differentiate bacterial causes from aseptic causes (see Boxes 42.1 and 42.2). The type of bacteria isolated can lead to suspicion of the site of the predisposing condition. For example, *S. pneumoniae* or *H. influenzae* (or oral streptococci or anaerobic bacteria of oropharyngeal flora) is more common in patients with head trauma or congenital CSF communication to the middle ear, nose, or sinuses, whereas *N. meningitidis* suggests a complement deficiency. Recurrent pneumococcal infection, including meningitis, can occur in individuals with agammaglobulinemia, IgG subclass deficiency, early complement deficiency (C2–C4), HIV infection, or asplenia.[1] If *S. aureus,* coagulase-negative staphylococci, *Corynebacterium* spp., enteric or environmental gram-negative bacteria, anaerobic bacteria, or a combination of such organisms is isolated, a dermal sinus should be suspected. For polymicrobial gram-negative or anaerobic infections, a neurenteric defect or sequestration of bacteria in the CNS should be suspected.

Fluid suspicious for CSF rhinorrhea or otorrhea can be tested for glucose and protein using multireagent strips. However, glucose testing often is unreliable with both false-negative and false-positive results reported. The β_2-transferrin assay has been used for decades as a first-line screening method for CSF leaks. More recently, the β-trace protein (βTP) test has been used to detect CSF leaks. βTP is produced mainly in the leptomeninges and choroid plexus but also serum and is secreted into CSF. The test should not be used in patients with renal insufficiency or bacterial meningitis because these conditions increase serum concentrations and decrease CSF concentrations of βTP.[52] Both β_2-transferrin and βTP are reliable markers for the detection of CSF leak.[53]

Several imaging methods are available for the evaluation of suspected CSF fistulas and other anomalies. Plain radiography can detect large defects or abnormalities. CT and magnetic resonance imaging (MRI) are more precise for localizing smaller lesions; multiple thin-cut coronal views must be obtained because small defects can be missed in axial views. Use of dyes or contrast material (Fig. 42.7) is helpful in visualizing smaller bony defects.[54] Radionuclide cisternography (RC) alone or in combination with pledgets placed in the nostrils or ears is considered by some to be the method of choice for localizing occult CSF fistulas in the skull.[17] RC using diethylenetriamine penta-acetic acid (DTPA), labeled with either technetium-99m or indium-111, allows for up to 72 hours of observation, increasing the detection of slow or intermittent CSF leaks.[55]

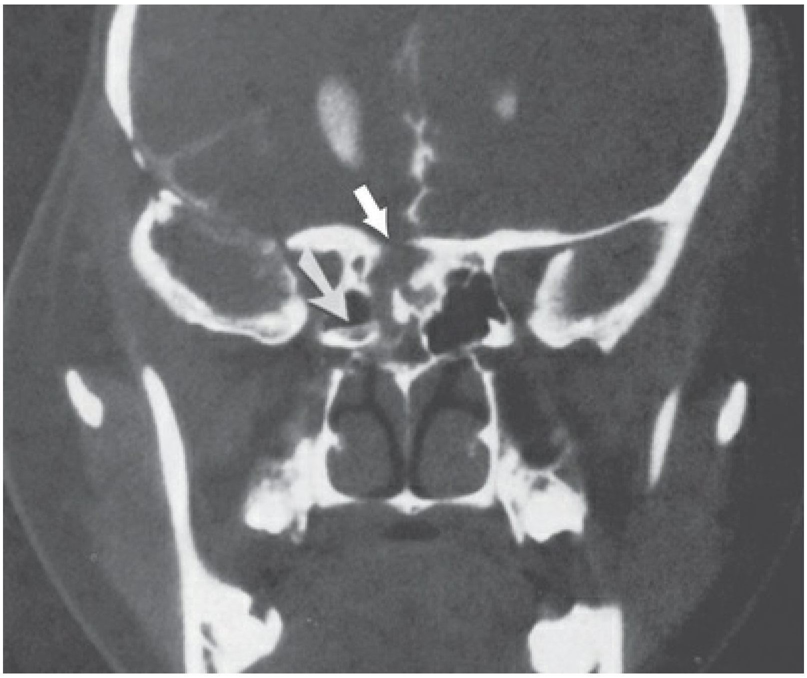

FIGURE 42.7 Coronal computed tomography with intravenous contrast enhancement showing defect in the bone *(gray arrow)* and collection of contrast material with fluid level *(white arrow)* in the sphenoid sinus. (Courtesy of S. E. Byrd, MD, Children's Memorial Hospital, Chicago.)

The initial screening test for complement deficiencies is the total hemolytic complement (CH50) assay. A low CH50 assay value suggests that one or more of the classical or terminal components is missing. CH50 may be within normal range if only C3 or C4 is abnormal. If there is high suspicion for complement deficiency, individual components may need to be tested despite a normal CH50. If the complement cascade is intact, analysis of quantitative serum immunoglobulins and subclasses is warranted. Imaging of the abdomen (e.g., ultrasound or splenic scan) can be performed to rule out hyposplenism or asplenia. If Mollaret meningitis is suspected, CSF PCR for HSV is useful. In addition, the serum/CSF ratio of antibodies for HSV can be done if PCR is negative.[56]

Treatment

For recurrent bacterial meningitis due to head trauma, congenital malformations, or complement deficiency, the choice of empiric antibiotic therapy should be similar to that for single-episode meningitis. For patients with a known dermal sinus or history of meningitis due to staphylococcal or gram-negative bacteria, an antibiotic with a broader spectrum of activity but also targeting the identified pathogens is required. In rare cases when multidrug-resistant infections have not responded to treatment intravenously, antibiotic has been administered intraventricularly,[57] although adverse effects can be related to such installations.

The length of therapy is normally the same as that for sporadic cases; there is no advantage to longer courses of therapy. Time to sterilization may be prolonged in cases of gram-negative bacillary infections associated with dermoid or epidermoid cysts because squamous collections can act like foreign bodies, so sterility of CSF should be documented by repeat lumbar puncture. Meticulous examination and diagnostic evaluation (occasionally including exploratory surgery) to identify and perform primary repair of the site of CSF fistula are most important. In the case of otorrhea, packing of the middle ear with fat is inadequate because it fails to close the fistula permanently. Even packing with muscle or fascia alone seems to be insufficient; additional grafting of the vestibule is needed. For CSF rhinorrhea, extracranial surgery may be the preferred technique, because of lower morbidity; the few disadvantages of this procedure are cranial nerve paralysis and postoperative sinusitis. In patients with Mollaret meningitis, initial anti-HSV therapy followed by long-term suppression (e.g., acyclovir) may be helpful.

Fresh frozen plasma has been given as replacement therapy to patients with complement deficiency. Although this may be reasonable in the few patients who suffer from life-threatening disease, routine administration of plasma can stimulate the production of antibodies against the missing component. Additionally, the short half-life of complement proteins makes this approach impractical. Weekly or monthly immunoglobulin infusions for patients with immunoglobulin subclass deficiency should be individualized according to the severity of the disease (i.e., recurrent bacterial vs. aseptic meningitis).

Prevention and Prophylaxis

Imaging of the temporal bone should be considered in children with idiopathic sensorineural hearing loss to identify those who have an inner-ear anomaly. Parents of children with proven inner-ear anomaly should be educated about the risk for recurrent meningitis from middle-ear infection, contact sports, and activities that may increase the inner- or middle-ear pressure (e.g., diving, prolonged Valsalva maneuver). Suspected middle-ear infections should be treated promptly and aggressively, and in patients with common cavity abnormalities, exploratory tympanotomy should be considered. If cochlear implantation is considered in patients with inner-ear malformation, the type of implant, the risk for meningitis, and preprocedure immunization should be discussed.[58] All efforts should be made to identify and seal CSF leaks because continued leakage increases the risk for postoperative meningitis.[59]

Although prophylactic antibiotics often are given to patients with recurrent meningitis, their efficacy in preventing further episodes is questionable. Antibiotic prophylaxis has been prescribed to prevent meningitis associated with basilar skull fracture. However, a 2006 Cochrane review concluded that prophylactic antibiotics had no effect on the prevention of meningitis in these patients.[60] In addition, one review suggested that antibiotic prophylaxis after basilar skull fracture could be harmful because of increased risk for infection due to antibiotic-resistant organisms.[61] Prophylactic antibiotics have been used in patients with complement or significant immunoglobulin subclass deficiency. In some cases, such treatment markedly reduced the incidence of infection, yet the clinical failure of penicillin prophylaxis against meningococcal disease suggests that long-term prophylaxis may have limited value.[29] The advisability of antibiotic prophylaxis in patients with recurrent meningitis should be made on a case-by-case basis; firm guidelines are not available. Limited data suggest that chronic oral acyclovir (for 1 year or more) may prevent recurrences of Mollaret meningitis.[62]

Vaccination with an age-appropriate meningococcal conjugate vaccine against meninogoccal serogroups A, C, Y, and W 135 is recommended for children aged 2 to 23 months who are at increased risk for meningococcal disease (i.e., those with persistent complement deficiencies such as C3, C5–C9, properidin, factor D, and factor H, and those with functional or anatomic asplenia, including sickle cell disease)[63] Individuals aged 2 to 55 years with high-risk conditions who were not previously vaccinated are also recommended to receive meningococcal vaccine. Booster doses are required (see Chapter 125.) Two serogroup B menigococcal vaccines were recently approved for use in persons 10 to 25 years of age with increased risk for meningococcal disease.[64] A quadrivalent meningococcal polysaccharide vaccine (MPSV4) is approved as a single dose in persons aged ≥2 years but is not currently recommended for children and largely is supplanted by conjugate vaccine.

Pneumococcal conjugate vaccine (PCV13) currently is recommended for prevention of invasive pneumococcal disease (IPD) in all children beginning at 2 months of age.[65] In addition, children 2 years of age or older and adults in high-risk groups for IPD (e.g., patients with CSF leak, functional or anatomic asplenia, or cochlear implant, or who are immunocompromised) also should receive pneumococcal polysaccharide vaccine (PPSV23). Ideally, children should complete age-appropriate pneumococcal vaccines (PCV13 followed by PPSV23) at least 2 weeks before implantation of a cochlear device because these children have a significantly increased risk for pneumococcal meningitis.[66] A second dose of PPSV23 5 years after the first dose is recommended for children with immunocompromising conditions. Children with a cochlear implant are recommended to receive a single dose of PPSV23 (after PCV vaccination). Failure of pneumococcal vaccines to prevent recurrent episodes of meningitis in predisposed individuals can occur.[67] Education of families to seek immediate medical attention for illness is critical.

Aseptic and Viral Meningitis

Jin-Young Han, José R. Romero

The term *acute aseptic meningitis* was introduced in 1925 to describe a self-limited central nervous system (CNS) syndrome characterized by acute onset of fever and meningeal irritation in which the cerebrospinal fluid (CSF) exhibited a mononuclear pleocytosis and was bacteriologically sterile.[1] With advances in diagnostic methodologies it is now recognized that multiple infectious agents, drugs, and localized and systemic inflammatory conditions can cause aseptic meningitis (AM) syndrome (Box 43.1).[2,3]

Box 43.1

Major Causes of Aseptic Meningitis Syndrome

Common

Enteroviruses A–D (echoviruses, coxsackieviruses, numbered enteroviruses)

Human parechoviruses

Arboviruses (Western equine encephalitis virus, St. Louis encephalitis virus, Colorado tick fever, La Crosse encephalitis virus, West Nile virus, tickborne encephalitis virus, Toscana virus)

Borrelia burgdorferi

Partially treated bacterial meningitis

Uncommon

Herpes simplex virus type 2

Mumps virus

Human immunodeficiency virus

Mycobacterium tuberculosis

Parameningeal bacterial infection

Fungi *(Cryptococcus, Coccidioides, Histoplasma, Blastomyces)*

Rare

Respiratory viruses (adenovirus, influenza, parainfluenza)

Lymphocytic choriomeningitis virus

Other herpesviruses (herpes simplex virus type 1, human herpesvirus 6, Epstein-Barr virus, varicella-zoster virus, cytomegalovirus)

Measles virus

Miscellaneous viruses (parvovirus B19, rotavirus)

Bartonella spp. (cat-scratch disease)

Spirochetes

Leptospira spp.

Brucella spp.

Parasites (e.g., *Taenia solium* (cysticercosis), *Toxoplasma gondii, Trichinella spiralis* [trichinosis])

Mycoplasma pneumoniae

Rickettsia spp.

Noninfectious Causes

Drugs (e.g., nonsteroidal anti-inflammatory agents, agents instilled into cerebrospinal fluid)

Biologic products (e.g., immune globulin, OKT3)

Systemic immunologically mediated diseases (e.g., rheumatologic diseases, Behçet disease)

Neoplastic diseases

Viral meningitis can be described as a CNS infection that is associated with signs of meningeal irritation (i.e., neck stiffness, Kernig and Brudzinski signs) but not neurologic dysfunction as a result of brain parenchymal involvement. In contrast, viral encephalitis is a CNS disorder with evidence of brain parenchymal dysfunction as manifest by an altered state of consciousness or other objective signs of neurologic dysfunction (e.g., seizures, cranial nerve palsies, abnormal reflexes, paralysis). Although commonly discussed as separate syndromes, overlap (meningoencephalitis) occurs frequently. This chapter focuses on viral agents more commonly associated with acute aseptic meningitis.

Etiologic Agents and Epidemiology

Because aseptic meningitis is not a reportable disease in the United States, the total annual cases and incidence are unknown. The estimated annual number of aseptic meningitis cases is believed to be at least 75,000. In Olmsted County, Minnesota, the incidence of aseptic meningitis over 32 years was found to be 10.9 per 100,000 person years.[4] The highest rates occurred in infants, toddlers, and children. The Centers for Disease Control and Prevention (CDC) reported that over a 10-year period the incidence of aseptic meningitis ranged from 1.5 to 4 per 100,000.[5] The differences in incidences may be the result of underreporting owing to a passive reporting system used by the CDC. In Finland, a 14-year birth cohort study found the annual incidence of viral meningitis to be 27.8 per 100,000.[6] The highest rates were observed in infants and children <4 years of age.

Before the advent of cell culture, a specific etiology of aseptic meningitis was identifiable in only 25% of cases.[7,8] Cell culture led to a substantial improvement in the identification of viral causes of aseptic meningitis, primarily owing to identification of enterovirus (EV). Using cell culture in addition to animal inoculation and serology, the etiology of aseptic meningitis could be established in ~55% to 70% of cases.[9–11] Cell culture clearly established EV as the dominant etiology of aseptic meningitis, accounting for ~55% to 90% of all identifiable causes.[4,9–12] Use of vaccines for prevention of mumps and polio led to nonpolio EVs becoming the overwhelming dominant cause of aseptic meningitis.[4,9–12] Nucleic acid amplification tests (NAATs) continue to support their significant etiologic role.[13–15]

Enteroviruses and Parechoviruses

EVs are members of the Picornaviridae family of viruses.[16] Four species (enteroviruses A–D), encompassing more than 100 confirmed or putative serotypes, are recognized within the genus.[16]

EVs have a worldwide distribution. Although >100 serotypes comprise the genus, only a few cause disease each year. The dominant serotypes vary geographically and temporally.[17–21] In regions with temperate climates, EV infections exhibit a strong seasonal epidemiology, occurring primarily in the summer and fall.[17–19] In topical and subtropical regions, infections occur year-round with increased incidence during the rainy season.

The use of NAAT has demonstrated that >70% of aseptic meningitis cases in children for which an etiology is identified are attributable to EV.[13–15,22] Given their significant contribution as causes of aseptic meningitis, it is not surprising that the seasonal occurrence of aseptic meningitis parallels activity of these viruses (Fig. 43.1).

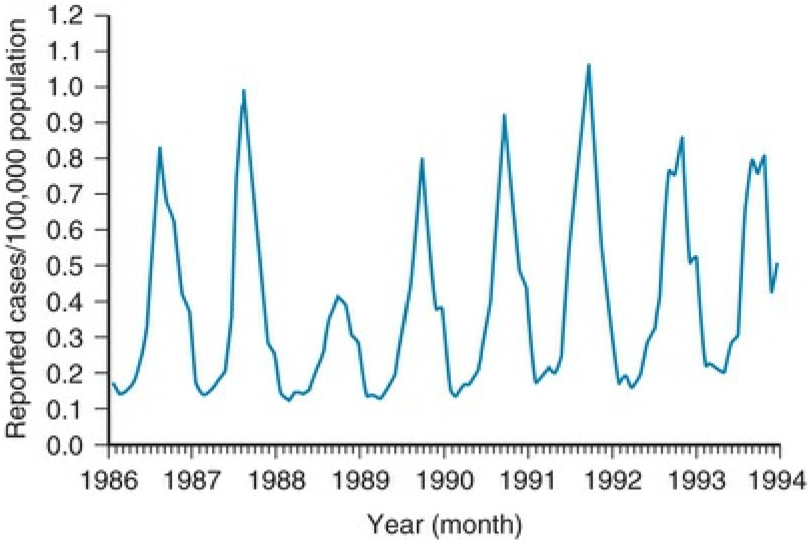

FIGURE 43.1 Seasonal incidence of aseptic meningitis in the United States from 1986 to 1993, as reported to the Centers for Disease Control and Prevention. The summer predominance reflects the role of enteroviruses as the leading cause of the aseptic meningitis syndrome. (Redrawn from Centers for Disease Control and Prevention. Summary of notifiable diseases, United States, 1993, MMWR 1994;42:69.)

Parechoviruses, also in the family Picornaviridae, are recognized causes of aseptic meningitis.[23–25] Initially classified as EVs, biologic, antigenic, and genomic differences led to their reclassification into a novel genus.[16,26] Most human parechovirus (HPeV) infections occur during the summer and fall. HPeV type 3 is the dominant type associated with aseptic meningitis and has been identified in an average of 5% to 7% of EV-negative archival CSF specimens,[23,24] with higher rates in very young infants evaluated because of fever, sepsis-like, or neurologic symptoms.[27–29]

Arboviruses

The arboviruses comprise a group of >500 viruses from multiple viral families transmitted by an arthropod vector.[30] Human-to-human transmission is rare and is the result of blood, organ, or maternal-fetal/infant transmission. Mosquitoes are the vectors for most clinically significant arboviruses endemic to North America. Notable exceptions include Colorado tick fever (CTF) and Powassan virus (POWV), as well as, in Eurasia, tickborne encephalitis virus (TBEV), which are transmitted by ticks.[31,32] TBEV infection also can occur through consumption of infected unpasteurized milk.[32] In the Mediterranean region, sand flies serve as the vectors for Toscana virus (TOSV).[33] The peak incidence of arboviral infections coincides with the periods of maximal activity of their vectors. In North America this is summer and fall.

Most arboviruses associated with aseptic meningitis in North America are members of the Flaviviridae family. Neurotropic Flaviviridae include Japanese encephalitis virus, West Nile virus (WNV), St. Louis encephalitis (SLE) virus, Murray Valley encephalitis virus, and the tickborne encephalitis virus (POWV, CTF, TBEV) complexes.

WNV is the most common cause of arboviral infection in North America. However, <1% of infections in adults and children result in CNS disease. In the United States, children account for 4% of WNV neuroinvasive disease (WNND). Meningitis is the most common manifestation in children, accounting for ~50% of cases.[34] Cases of WNND in children have been reported from most states in the US and multiple countries worldwide.[34,35] The median annual incidence is 0.07 cases per 100,000 children.[34] South Dakota, Wyoming, North Dakota, and Nebraska, in decreasing order, have the highest median annual incidence (0.52 to 1.04 per 100,000 children).

SLE virus was first recognized in 1933 and is widely distributed throughout the American continent.[36,37] Epidemics or sporadic cases have been reported in virtually every state in the US. A mean of 4.25 cases of SLE neuroinvasive disease (SLEND) were reported annually from 2006 to 2008.[38] The reported rate of SLE in 2008 for children aged 1 to 14 years was 0.02 per 100,000.

Three neurologic syndromes have been reported with SLEND: encephalitis, aseptic meningitis, and febrile headache.[39] Aseptic meningitis accounts for ~40% of SLEND cases in children. In Japan and Asia, a related flavivirus, Japanese encephalitis virus, can cause aseptic meningitis in children.[40]

In Europe, TBEV is an important cause of aseptic meningitis.[32] Three subtypes exist: European, Siberian, and Far Eastern. The European and Siberian subtypes can cause meningitis, encephalitis, or myelitis. Aseptic meningitis constitutes ~60% to 70% of pediatric TBEV CNS disease.[41,42] TBE occurs primarily from March to November. The reported incidence in Swiss children is 1 per

100,000.[41] In Slovenia, the annual incidence varies from 3.7 to 24.6 per 100,000; 12% to 27% of cases occur in children <15 years of age.[43] Although not endemic to North America, cases have occurred in persons returning from Europe and China.[44]

In North America, POWV, a related virus, causes occasional cases of aseptic meningitis.[31] The tickborne CTF virus in the Reoviridae family also can cause aseptic meningitis.[44,45]

La Crosse virus (LACV) is in the family Bunyaviridae. In the US, LACV was the most common etiology (55%) for pediatric neuroinvasive arboviral disease from 2003 to 2012, with an annual incidence of 0.09 per 100,000 persons.[34] About 88% of LACV CNS disease occurs in children <18 years of age.[34] Aseptic meningitis accounts for 20% of children with CNS disease caused by LACV.[34]

Toscana virus (TOSV) belongs to the *Phlebovirus* genus within the Bunyaviridae family. It is increasingly recognized as an etiologic agent for aseptic meningitis in the Mediterranean area.[33]

Paramyxoviruses

Multiple Paramyxoviridae, including measles, mumps, and parainfluenza viruses, can cause CNS infection.[46] In mumps, aseptic meningitis occurs as complication in 0.5% to 15% of cases, and CSF pleocytosis is seen in >50% of patients with mumps parotitis.[47,48] In North America, before mumps vaccine, mumps caused 2.5% to 15% of all aseptic meningitis cases and 17.5% to 22% of known causes of meningitis.[4,9–12,49] In countries where mumps remains endemic, meningitis continues to occur.[50,51] During each of two recent US outbreaks, cases of meningitis were reported.[52,53] There are >10 mumps vaccine strains used around the world.[54] Although the Jeryl Lynn and its related vaccine strains (used exclusively in the US) rarely, if ever, cause aseptic meningitis, other vaccine strains have been associated with varying incidences of aseptic meningitis.[54]

Parainfluenza viruses can cause aseptic meningitis.[46] The dominant serotype identified has been type 3. Measles infection can be associated with pleocytosis, usually without signs or symptoms of meningitis.[55]

Arenaviruses

The arenavirus lymphocytic choriomeningitis virus (LCMV) was identified as a cause of aseptic meningitis in 1935.[56,57] Although previously a major cause of aseptic meningitis,[8,9] owing to undefined epidemiologic factors or, perhaps, lack of testing, LCMV meningitis is now uncommon. Rodents, particularly the common house mouse, are its natural reservoirs; hamsters and guinea pigs also are capable hosts.[57] LCMV is shed in rodent excreta and secretions throughout the animal's life. Human infection occurs through contact with LCMV-contaminated fomites or inhalation or ingestion of aerosolized virus. The highest incidence of infections is seen during the late fall and winter.

Herpesviruses

Virtually every member of the human herpesviruses has been associated with aseptic meningitis in children.[58–61] Notable among these are varicella-zoster virus (VZV) and herpes simplex virus 2 (HSV-2). VZV-related meningitis has been reported in immunocompetent children during primary infection and reactivation.[59,60] Cases of aseptic meningitis associated with the vaccine strain of VZV (Oka strain) have been reported.[60,61] The use of NAAT has allowed the identification of VZV-associated meningitis in zoster cases lacking cutaneous lesions.[62,63]

Use of NAATs has documented HSV-2 and, less commonly, HSV-1 as causes of meningitis in children and adolescents.[64–67] HSV-2 infection can cause primary or recurrent aseptic meningitis. The latter occurs more frequently in women.

Other Viruses

Various other viruses, including parvovirus B19,[68] adenovirus aseptic meningitis,[10] rotavirus,[69,70] influenza A and B viruses,[71] and human immunodeficiency virus, occasionally have been identified as causes of aseptic meningitis.[72]

Other Etiologies

Less commonly, certain bacteria not readily visualized in stains of CSF or grown in standard culture systems, such as *Borrelia, Treponema,* and *Rickettsia* spp., mycoplasma, and fungi, can cause aseptic meningitis syndrome) (see Box 43.1). Additionally, various paramenigeal processes, neoplasms, systemic illnesses, drugs, and noninfectious etiologies can result in an aseptic meningitis syndrome.[3,73]

Pathogenesis and Pathology

Most of what is known regarding the pathogenesis of EV infections has been derived from the study of the polioviruses.[74,75] EVs are transmitted primarily by the fecal-oral route and, less commonly, by respiratory droplets and transplacentally. After ingestion, infection and replication occur in the nasopharynx and lower gastrointestinal tract. Replication at these sites results in a minor or primary viremia that seeds multiple organs, including the CNS, liver, lungs, and heart. Further replication at these sites produces a major or secondary viremia. The CNS can be seeded during the initial viremic phase or during the major viremia. Viremia continues until the host develops type-specific antibodies.

The exact means by which polioviruses and other EVs enter the CNS is unclear, and multiple routes have been proposed.[74,75] Infection of endothelial cells expressing specific receptors may facilitate CNS entry. Infection of mononuclear cells may allow CNS access through a “Trojan horse” mechanism. Access to the CNS also can occur by axonal retrograde transport from the peripheral nervous system.

The pathogenesis of arbovirus infections begins with vector-mediated intradermal inoculation of the virus.[32,76] Viral replication occurs at the site of inoculation. For some flaviviruses, replication occurs in Langerhans dendritic cells, which migrate to the regional lymph nodes. Viral replication continues in the regional lymph nodes, followed by a viremia that seeds the entire reticuloendothelial system. Viremia results in infection of multiple organs, including the brain. The mechanism by which arboviruses enter the CNS is not known. For some, infection of cerebral microvascular endothelial cells or transneural spread after infection of the olfactory bulb are modes of entry. Viremia persists until the host develops type-specific antibodies.

Because of the generally favorable outcome of aseptic and viral meningitis, histopathologic data are scarce. The histopathology of

EV aseptic meningitis characteristically shows varying degrees of edema and lymphocytic infiltration of the meninges.[77] Perivascular lymphocytic cuffing may be seen within the cerebral parenchyma as well as the presence of neutrophils. Demyelination near blood vessels (suggesting an autoimmune process) and evidence of acute parenchymal involvement have been observed in the rare fatalities associated with mumps meningitis.[78]

Clinical Manifestations

The clinical manifestations of enteroviral meningitis vary with age of the patient. Regardless of age, clinical findings of meningitis can coexist with clinical findings of other syndromes (e.g., myocarditis, pericarditis, pleurodynia, hand-foot-and-mouth syndrome).

Neonates can come to attention with abrupt onset of fever and irritability. Poor feeding and lethargy can occur. Physical examination can reveal a bulging or full fontanel. Exanthems occasionally are present. Nuchal rigidity is uncommon.[79–81] In severe cases, evidence of involvement of other organ systems can be dominant (i.e., hepatitis, myocarditis, pneumonitis, disseminated intravascular coagulopathy).[81]

In infants and children, fever of abrupt onset is the most common presenting sign.[82–85] In some, the fever pattern and clinical course are biphasic.[82,86] In infants, nonspecific symptoms such as irritability, lethargy, poor feeding, emesis, or diarrhea can be present.[84,87,88] In older children, additional nonspecific findings include generalized malaise, sore throat, abdominal pain, nausea, myalgia, and exanthems. Physical findings may include nuchal rigidity and Brudzinski and Kernig signs. Less than 10% of infants <3 months of age exhibit these findings, which increase in frequency with advancing age.[83,87] In children able to report it, headache is almost always present and may be temporarily relieved by the performance of a lumbar puncture.[88,89] Photophobia is common. Seizures occur in <5%.[87,90] When the presentation exhibits a biphasic course, nonspecific signs and symptoms are followed by a brief period of improvement and then with evidence of neurologic involvement.[82,91]

In adolescents and adults, headache usually is present.[92–95] Fever, photophobia, signs of meningeal irritation, nausea, emesis, and neck stiffness occur in most patients. Myalgia is common. Abdominal pain and exanthems also are reported occasionally.

The clinical presentation of HPeV aseptic meningitis in infants parallels that of the EVs with several notable differences.[24,96] Gastrointestinal (vomiting, diarrhea) or respiratory symptoms (cough, tachypnea, wheezing, apnea) occur in up to half of cases. Neurologic symptoms and a sepsis-like syndrome consisting of fever, tachycardia, poor perfusion, and irritability occur with varying frequency.[27–29]

Typically, in children with mumps parotitis, the onset of meningitis occurs during the first week of illness. However, aseptic meningitis can precede parotitis by a week or follow it by as much as 3 weeks.[46] Fever, headache, emesis, and meningeal signs are common.[8,97,98] Approximately 50% of patients have no evidence of parotitis. Additional symptoms include abdominal pain, diarrhea, and sore throat.

The clinical findings of arbovirus meningitis are not sufficiently unique to distinguish it from other viral meningitides. The signs and symptoms of WNV meningitis in children are similar to those reported in adults.[99] The onset is abrupt with fever, headache, and neck stiffness and Kernig and Brudzinski signs. Photophobia, phonophobia, and weakness can be present. Additional symptoms can include nausea, vomiting, diarrhea, sore throat, cough, rash, and lymphadenopathy.

TBEV meningitis has a biphasic course in approximately two thirds of children.[42,43] Onset is abrupt with fever, headache, malaise, abdominal pain, emesis, and arthralgia lasting 3 to 5 days. The second, symptomatic phase follows a 6- to 10-day period of recovery and is characterized by fever, headache, fatigue, emesis, and signs of meningeal irritation.

Aseptic meningitis due to TOSV has an abrupt onset with fever and headache, in children old enough to describe it. Nuchal rigidity is the most frequent physical finding. The presence of Kernig sign is variable.[100]

A biphasic illness also can be seen with CTF.[45] The initial phase consists of sudden onset of high fever, headache, emesis, and flu-like constitutional symptoms lasting 2 to 3 days. After 1 to 2 days of improvement, fever returns in association with nuchal stiffness and signs of meningeal irritation.

In HSV meningitis and HSV-2 recurrent benign lymphocytic meningitis, the onset of illness is acute with severe headache, neck stiffness, fever, photophobia, and emesis.[64,65,67] Most patients have no history of genital HSV infection.[65] Each episode lasts 1 to 3 days.[67] Multiple recurrences can occur.

The onset of LCMV meningitis is preceded by nonspecific symptoms suggestive of a viral upper respiratory tract illness and, occasionally, a rash. A brief period of improvement precedes the sudden onset of severe headache, nausea, emesis, photophobia, and myalgia. Physical examination reveals nuchal stiffness and signs of meningeal irritation.[2,8,56]

Differential Diagnosis

Borrelia burgdorferi (Lyme) meningitis has a high prevalence in endemic areas.[101,102] Longer duration of headache, predominance of CSF mononuclear cells, and cranial nerve palsy are suggestive of Lyme meningitis.[103,104] Endemicity, time of year, and history of erythema migrans or tick exposure are helpful in considering Lyme disease.

A small proportion (1%–2%) of children with untreated *Mycobacterium tuberculosis* infection develop meningitis.[105] Because symptoms early in the illness are vague and nonspecific, a high index of suspicion is required to make the diagnosis.

Treponema pallidum can cause aseptic meningitis during the secondary or tertiary phases of syphilis. Headache and signs of meningeal irritation can be present, or the patient may be symptom free.[106]

Meningitis associated with leptospirosis occurs during the immunologic phase of illness. In addition to typical signs of meningeal irritation, patients can exhibit rash, uveitis, conjunctival suffusion, and hepatosplenomegaly.[2] Aseptic meningitis complicates brucellosis in ~ 5% of cases.[107] *Mycoplasma pneumoniae, M. hominis, Chlamydophila pneumoniae,* and *Ureaplasma urealyticum* infections have been associated with aseptic meningitis.[108–111]

Parameningeal infectious foci (e.g., sinusitis, mastoiditis, vertebral osteomyelitis, epidural or subdural empyema) can manifest as aseptic meningitis. Rupture of intracranial dermoid or epidermoid cysts results in aseptic meningitis and can be recurrent.[112,113] Endocarditis may result in CSF abnormalities suggestive of aseptic meningitis.[114]

Aseptic meningitis occurs in up to 26% of children with Kawasaki disease and also can occur with Kikuchi disease.[115,116] Urinary tract infections in children have been associated with CSF pleocytosis in the absence of bacteria in the CSF.[117] Pleocytosis also can occur following complex migraines and prolonged seizures.[118,119] Aseptic meningitis has been associated with systemic illnesses such as sarcoidosis, systemic lupus erythematosus, Behçet disease, other connective tissue and vasculitis syndromes, and malignancies.[73]

Multiple medications and biologic agents can cause aseptic meningitis.[3] The major groups of drugs associated with drug-induced aseptic meningitis are nonsteroidal anti-inflammatory drugs (NSAIDs), antibiotics, immune globulin intravenous (IGIV), antiepileptic drugs, and immunomodulating agents. Aseptic meningitis related to NSAIDs is more commonly seen in women. Trimethoprim alone or in combination with sulfamethoxazole is the most common cause of antibiotic-induced aseptic meningitis. Antiepileptic drugs, most notably lamotrigine, also are associated with aseptic meningitis. Immunomodulating agents, including various monoclonal antibodies, chemotherapeutic agents, and intrathecal agents, are associated with aseptic meningitis.

Laboratory Findings and Diagnosis

The cytochemical analysis of the CSF is key to the diagnosis of aseptic meningitis. Pleocytosis is a prerequisite and typically is lymphocytic in character, ranging from 100 to 1000 cells/mm^3.[8,42,43,46,64,65,79,84,87,90,97] Count can exceed 2000 cells/mm^3 in some cases of LCMV, EV, and mumps meningitis.[46,57] In most cases of HPeV meningitis, detection of virus occurs in the absence of pleocytosis.[24,96] If the CSF is examined early in the illness, particularly with enteroviral meningitis, polymorphonuclear pleocytosis can predominate.[86,87,90,120] Reexamination several hours to days later reveals a shift toward lymphocytic predominance.[86,91,121] Eosinophilic pleocytosis has been reported with EV meningitis.[122]

The CSF protein concentration generally is mildly to moderately elevated, whereas the glucose concentration usually is normal.

Hypoglycorrhachia occurs in up to one fourth of LCMV and mumps meningitis cases as well as sporadic cases of EV and HSV-2 meningitis.[46,57,90,97,120,122]

Traditionally, the diagnosis of EV meningitis has relied on cell culture detection of virus from CSF.[123] NAATs are significantly more sensitive and rapid; they have become the standard for detection of EV in CSF, and timely results can reduce length of hospital stay and antibiotic use.[123–125]

In neonates with suspected EV meningitis, blood, CSF, and rectal swab or stool samples can be submitted for cell culture. Viral shedding from mucosal sites infers recent infection. The same is not true in older patients, who can shed EV from mucosal sites for weeks to months after infection.

Serologic confirmation of EV infection generally is impractical and not useful in acute management.[123]

NAATs are the methodology of choice for the diagnosis of parechovirus meningitis.[24]

Because the sensitivity of CSF culture for HSV is too low to be of clinical utility, NAAT detection should be used.[64,65,67] Detection of HSV antibodies in CSF should not be used to confirm the diagnosis of HSV meningitis.[66] Inflammation of the blood-brain barrier can permit serum HSV antibodies to cross into the CSF, resulting in a false-positive assay. CSF NAAT also should be used to detect other herpesviruses (VZV, EBV, CMV, human herpesvirus 6).

The diagnosis of arbovirus meningitis relies on the detection of virus-specific antibodies.[30,31] Immunoglobulin M (IgM) or IgG capture immunoassay or immunofluorescence typically is used; antibody capture format is more sensitive than other methods for IgM detection. Hemagglutination inhibition and complement fixation tests mainly are used for research.

The approach to the diagnosis of any arbovirus meningitis generally follows that used for WNV.[30,31] Because the presence of arbovirus-specific IgM antibodies in CSF infers intrathecal production, this test should be performed to diagnose WNV meningitis. WNV-specific IgM antibodies usually are present in the CSF by days 3 to 5 of illness.[30] Serum IgM appears 3 days later. Although the finding of specific IgM in CSF is considered diagnostic, detection in serum is not because IgM anti-WNV can be present for >2 years after infection.[126] Prolonged false-positive result of serum IgM anti-WNV also can occur with SLE virus. Because of cross-reactions with related viruses, a positive IgM anti-WNV assay result should be followed by a virus-specific neutralization test.

If only serum is available for testing, an arbovirus-specific cause can be established by documenting rising titers. Although serum NAAT can detect WNV early in infection, by the time CNS symptoms appear, NAATs are less sensitive than antibody tests because of rapid clearance of the virus.[30]

The appearance of antibodies to CTF virus occurs late in the illness (10−14 days after onset of symptoms), limiting the value of serology for diagnosis.[31,127] NAAT permits early (within 5 days of onset) detection of CTF virus. Detection of intraerythrocyte CTF virus using immunofluorescence staining is possible, but interpretation is subjective. Virus isolation using cell culture or animal inoculation is possible. However, the latter is rarely used.

The diagnosis of mumps meningitis can be made by virus isolation, documentation of significant convalescent antibody titers, presence of mumps-specific IgM antibodies, or NAAT detection of mumps genome.[128] Mumps virus can be isolated from saliva, blood, urine, and CSF. The virus may be present in saliva 9 days before and 8 days after the onset of parotitis and in urine for up to 2 weeks after the onset of symptoms. Serum IgM antibodies to mumps virus is present within 3 to 4 days of the onset of symptoms and can persist for up to 3 months.[128] A single serum sample obtained within 10 days of the onset of illness documenting the presence of IgM antimumps virus is sufficient to establish the diagnosis. IgG antibodies are detectable 7 to 10 days after symptom onset and persist for life. Antibodies to other paramyxoviruses can cross-react with mumps serologic assays, leading to false-positive results.

Management and Empiric and Definitive Therapy

When it is not possible to exclude a bacterial etiology, hospitalization and empiric antibiotic therapy are initiated while awaiting results of bacterial cultures of CSF and NAAT. Hospitalization usually is not necessary for patients who appear well and have CSF findings that are not suggestive of a bacterial infection.

Treatment of viral meningitis is supportive. Antipyretics, intravenous fluids, and narcotic analgesic may be indicated. Anticonvulsants may be used to manage seizures should they occur, but a need for prolonged use is uncommon.

No antiviral therapies approved by the US Food and Drug Administration (FDA) are available for most viral causes of meningitis. Reports of the use of immune serum globulin, maternal serum or plasma, or commercial IGIV in severe neonatal enteroviral disease have been published.[81] No definitive conclusions can be derived from these reports.[81]

Pleconaril, an antiviral compound that inhibits EV uncoating and blocks viral attachment to host cell receptors,[129] failed to meet criteria for FDA licensure for uncomplicated aseptic meningitis.[75]

Acyclovir is the drug of choice for the treatment of HSV encephalitis. However, the benefit of acyclovir and its derivatives (valacyclovir and famciclovir) in the therapy of HSV-related meningitis and recurrent meningitis (unlike HSV encephalitis) remains unproved.[67]

Complications, Prognosis, and Sequelae

Complications of EV meningitis are reported in ~10% of infected patients and include coma, increased intracranial pressure, and inappropriate secretion of antidiuretic hormone.[87,121] EVs require antibody-mediated mechanisms for their elimination. EV in individuals with agammaglobulinemia or hypogammaglobulinemia can lead to chronic meningitis or meningoencephalitis that persists and progresses over many years, often with a fatal outcome.[131]

Beyond the neonatal period, EV meningitis rarely has a poor outcome, but recovery can be prolonged.[80,92,95,132] The incidences of morbidity and mortality due to perinatal EV infections may be as high as 73% and 10%, respectively.[81] Death usually is the result of hepatic failure or myocarditis. The long-term prognosis for young children with EV meningitis is good; no differences in neurodevelopmental testing between patients and controls were reported in one large study.[87] In children and infants the duration of illness generally is ≤1 week. In adolescents and adults the time to complete recovery is 2 to 3 weeks.[92,95]

Mumps meningitis is benign with minimal risk for mortality or long-term sequelae. A review of ~200 cases of mumps aseptic meningitis revealed that all recovered without sequelae and none developed deafness.[46] Hydrocephalus complicating mumps meningitis has been reported but occurs rarely.[46] Occasional deaths have occurred in children with mumps meningoencephalitis.

Arboviral meningitis in children generally is associated with an excellent prognosis. The mortality rate for reported cases of WNND in the US over a 10-year period was <1%.[34,35] Recovery from WNV meningitis appears to be complete.[33] Long-term sequelae in Western forms of TBEV are infrequent, and virtually all pediatric patients with meningitis recover fully.[32,41,42] The duration of TOSV meningitis is ~7 days, with almost patients all exhibiting complete recovery.[33,100]

Individuals with HSV-2 primary meningitis or recurrent benign lymphocytic meningitis can exhibit transient neurologic findings that include seizures, hallucinations, diplopia, and cranial nerve palsies.[64,66] Less commonly, patients may be drowsy or have altered mental status. Failure of any of these symptoms to resolve should call into question the diagnosis. Recurrent episodes can occur, but recovery occurs without sequelae.[67]

Meningitis due to LCMV has a benign course lasting 10 to 14 days, with complete recovery in immunocompetent individuals.[67]

Prevention

The use of vaccines for the prevention of poliomyelitis and mumps has dramatically reduced these agents as causes of aseptic meningitis. Several effective vaccines for prevention of TBEV are available in Europe and Russia.[32]

Handwashing prevents the spread of EVs. In patients with inherited antibody deficiency, therapy with IGIV reduces the risk for chronic meningitis.

Use of insect repellents and appropriate clothing and avoidance of areas known to be mosquito-, flea-, or tick-infested help decrease the risk for arbovirus infection. Routine maintenance of screens and house integrity decreases the risk for exposure to mosquito-borne arboviruses and murine LCMV.

Suppressive therapy with acyclovir, valacyclovir, and famciclovir has been used to control HSV-associated recurrent meningitis. Regardless of a history of genital lesions, individuals with HSV-2 meningitis should receive counseling regarding genital herpes and the possibility of transmission of infection; prepubertal children should be evaluated for sexual abuse.[67]

Encephalitis

Carol A. Glaser, Karen C. Bloch

Encephalitis refers to inflammation of the brain parenchyma; typical signs and symptoms include fever, headache, and alteration in consciousness. Alteration in consciousness distinguishes encephalitis from uncomplicated meningitis, which features typically include fever, headache, and nuchal rigidity but lack global or focal neurologic dysfunction. Encephalitis is one of the most challenging conditions for clinicians to diagnose and manage because of the severity of illness, the vast number of potential etiologies, lack of an identifiable etiology in most cases, and ineffective treatment options for many causes. Without the identification of a neurotropic agent or analysis of brain tissue, the diagnosis of encephalitis is presumptive and is based on clinical features.[1] Patients with encephalitis can manifest parenchymal brain findings alone, but most have associated meningeal inflammation, thus representing the overlap syndrome termed *meningoencephalitis*. For the purposes of this chapter, the terms *encephalitis* and *meningoencephalitis* are used interchangeably. Encephalitis is a major healthcare cost. Total charges for encephalitis-associated hospitalizations in the United States in 2010 were estimated to be $2 billion.[2] This chapter focuses predominantly on viral causes of encephalitis in the immunocompetent host, but other pertinent agents and special hosts also are considered.

Etiologic Agents and Epidemiology

Although the term *encephalitis* often is used in conjunction with a viral etiology, bacteria, fungi, and parasites also are causative (Table 44.1), and a number of noninfectious conditions can mimic encephalitis (Box 44.1). Despite the multitude of infectious and noninfectious etiologies of encephalitis, no etiology is identified in more than 50% of cases.[2]

TABLE 44.1

Exposures Associated with Agents Causing Encephalitis and Encephalitis-Like Syndrome

Exposure and/or Reservoir	Agent	Risk Factors and Epidemiology
ARTHROPODS		
Mosquito	**Alphaviruses**	
	Chikungunya virus	Tropical Africa and Southeast Asia, Indian Ocean and parts of Europe, Caribbean countries, South and Central America
	Western equine encephalitis (WEE) virus	Summer and early fall onset; western US and Canada, Central and South America; rare cause of encephalitis, with 640 cases reported in the US from 1964 to 1999. There have been only 4 cases of neuroinvasive disease due to WEE since 1989, with no cases reported in the last 10 years (through 2009)
	Eastern equine encephalitis virus	Eastern and southern coastal states; children and elderly disproportionately affected; rare cause of encephalitis, with 260 cases reported in the US from 1964 to 1999
	Venezuelan equine encephalitis virus	Mexico, Central and South America; rarely in border states of US (Texas, Arizona)
	Semliki Forest virus	Africa
	Flaviviruses	
	West Nile virus	Emerging cause of epidemic encephalitis throughout US, Europe; endemic in Middle East; cases also found in Africa, Caribbean, India, Australia, Russia, and Southeast Asia; peak incidence adults >50 years
	Japanese encephalitis virus	Most common worldwide cause of encephalitis, endemic throughout Asia; vaccine preventable
	St. Louis encephalitis virus	Endemic to western US; with periodic outbreaks in central/eastern US, peak incidence in adults >50 years
	Murray Valley encephalitis virus	Australia and New Guinea
	Bunyaviruses	
	California/La Crosse virus	US with most cases in upper midwestern states (MN, WI, IA, IL, IN, OH) and more recently in mid-Atlantic and southeastern states (WV, VA, KY, NC, and TN); peak incidence in school-aged children
	Phleboviruses	
	Rift Valley Fever virus	Africa and Arabia

Tick	Powassan virus	In the US, endemic in the Upper Midwest, Great Lakes, New England, and New York; endemic in eastern Canada
	Anaplasma phagocytophila	Endemic to New England and north central and western US
	Ehrlichia ewingii	Endemic to southeastern and central US
	Ehrlichia chaffeensis	Endemic to northeastern US and Midwest
	Rickettsia rickettsii	Rocky Mountain spotted fever has been reported throughout the US with the exceptions of Hawaii and Vermont; states with highest incidence are Oklahoma, North Carolina, Arkansas, Tennessee, and Missouri
	Tickborne encephalitis virus	Endemic to Eastern and Central Europe, East and Southeast Asia
	Borrelia burgdorferi	Encephalitis in early disseminated Lyme disease; encephalopathy in late disease
	Kyasanur Forest disease virus	India
Sandflies	*Bartonella bacilliformis*	Colombia, Ecuador, and Peru
	Toscana virus	Italy, Mediterranean
	Chandipura virus	India
Tsetse flies	*Trypanosoma brucei gambiense*	West Africa and India; central nervous system (CNS) illness can occur years after infection
	Trypanosoma brucei rhodesiense	East Africa; CNS illness can occur years after infection
WILD OR DOMESTIC ANIMALS		
Bats	Rabies virus	Vaccine preventable. Between 1995 and 2009, 43 rabies cases were recognized in the US; 10 of these cases were imported (usually from a canine strain), and the remaining cases were acquired in the US mostly related to bat exposures and often with an unknown bite exposure
	Nipah virus	Epidemics in Southeast Asia; also found in Bangladesh and India. Reservoir host is fruit bat, but humans generally acquire disease through direct contact with infected swine
	Histoplasma capsulatum	Eastern and central US; occupational or recreational activities where there is exposure to disturbed soil, such as gardening; playing in barns, hollow trees, bird roosts, or caves; and examination, demolition, or renovation of contaminated buildings
Deer	*Borrelia burgdorferi*	Deer is reservoir host, but infection usually is transmitted to humans via tick vector
Elk	*Anaplasma phagocytophilum* *Brucella abortus*	Deer is reservoir host, but infection usually is transmitted to humans via tick vector Almost total eradication in cattle in the US, but the disease still occurs in some elk herds and wild bison in the western US
Dogs	Rabies virus	Vaccine preventable; dogs important in developing countries; worldwide distribution
	Toxocara canis	Dogs, especially puppies, shed eggs in feces, and organism survives in soil for prolonged period
Cats	*Bartonella henselae*	Typically follows scratch or bite from cat or kitten; highest incidence in children
	Toxoplasma gondii	Cats and other felines are reservoir hosts; they shed oocytes in feces, and the soil becomes contaminated. Sheep, goats, swine, cattle serve as intermediate hosts

	Rabies virus	Vaccine preventable; most common vector in the US is bat, and bites often unrecognized; cats are second to dogs in importance in developing countries; worldwide distribution
	Toxocara cati	Cats, especially kittens, shed eggs in feces, and organism survives in soil for prolonged period
Rodents	Lymphocytic choriomeningitis virus	Peak incidence in fall and winter; chronic infection in laboratory or house mice, hamsters, and guinea pigs; humans infected by inhalation or ingestion of dust or food contaminated by urine, feces, blood, nasopharyngeal secretions of infected rodents
	Leptospira spp.	Rodents (and other animals) excrete organism in urine, and the organism remains viable in soil or water for weeks to months
Raccoon	*Baylisascaris procyonis*	Pica, particularly near raccoon latrine
	Rabies virus	"Raccoon strain" extends along eastern seaboard of the US and has reached as far north as Ontario and New Brunswick in Canada
Sheep, goats	*Brucella melitensis*	Direct contact with infected animals or their secretions (note that *B. melitensis* eradicated in the US since early 1970s)
	Coxiella burnetii	Inhalation; either direct exposure to animal or exposure to contaminated materials (e.g., wool, straw)
Birds	*Cryptococcus neoformans*	Inhalation of soil contaminated with bird feces
	Chlamydophila psittaci	Healthy and sick birds can harbor and transmit organism to humans; usually acquired via inhalation of fecal dust/sections of birds
	West Nile virus	Birds are reservoir host, but infection usually is transmitted to humans via mosquito vector
Old World monkeys	Herpes B virus	Bite of Old World monkey (e.g., macaque)
Horses	Hendra virus	Endemic in Australia; associated with excretions/tissues from horses
Swine	Nipah virus *Brucella suis*	Epidemics in Southeast Asia; close contact with pigs No longer found in domestic swine but present in some wild hog populations
Skunks **Squirrel**	Rabies virus Bornavirus	Skunk populations are widely distributed in the US; cases found in California, Arizona, north central US, eastern coast of US Only 3 human cases described to date, exposure to squirrels in Germany
Parturient animals (especially farm animals)	*Coxiella burnetii*	Humans generally acquire via inhalation; either direct exposure to animal or exposure to contaminated materials (e.g., wool, straw)
INGESTION OR INHALATION		
Fresh water	*Naegleria fowleri*	Swimming or diving in warm, natural bodies of water (rarely poorly chlorinated pools reported)
	Leptospira spp.	Organisms excreted in animal urine or placental tissue and can remain viable for weeks to months in soil or water; recreational exposure associated with wading or swimming in contaminated water (particularly after floods)
Soil	*Balamuthia mandrillaris*	Contact with soil seems to be important risk factor, presumably through inhalation or inoculation
	Acanthamoeba spp.	Contact with soil seems to be important risk factor,

		presumably through inhalation or inoculation
	Baylisascaris procyonis	Pica, particularly near raccoon latrine; raccoons infected with *B. procyonis* appear to be common in many parts of the US; human cases reported in California, Oregon, New York, Pennsylvania, Illinois, Michigan, Georgia, Minnesota, and Missouri
	Coccidioides spp.	Also known as *Valley fever*. Infection is seasonal and is acquired by inhalation of soil or dust or laboratory acquired; endemic in certain areas of Arizona, California, Nevada, New Mexico, Texas, Utah, and northwestern Mexico. Also found in northern Argentina, northwest Brazil, Colombia, Paraguay, Venezuela, and Central America
	Histoplasma capsulatum	Inhalation of airborne spores from soil. Outbreaks have occurred in endemic areas with exposure to bird, chicken, or bat droppings or recently contaminated soil. Globally distributed, with the Ohio and Mississippi River basin, Mexico, and Central and South America being endemic areas in which as many as 80% of children have been infected. Also found in Africa, East Asia, Australia, and rarely in Europe
	Blastomyces dermatitidis	Endemic areas include the midwestern, southwestern, and south central US and the Canadian provinces near the Great Lakes and the St. Lawrence Seaway
	Toxocara canis/*T. cati*	Eggs in sandboxes and playgrounds; organisms survive long periods in soil
Undercooked pork or beef (rarely chicken)	*Toxoplasma gondii*	Consuming raw or undercooked infected meat; worldwide
Undercooked freshwater fish, chicken, or pork	*Gnathostoma* spp.	Southeast Asia and Mexico
Freshwater crayfish or crabs	*Paragonimus westermani*	Mostly in Asia but some reports from Africa and South America
Raw or undercooked meat	*Trichinella* spp.	Mostly associated with pigs but has been found in other mammals (e.g., horses, bear, foxes)
Frogs, snakes	*Gnathostoma spinigerum*	Southeast Asia and some areas in South and Central America
Raw or undercooked freshwater prawns, crabs, or frogs, or unwashed produce (with snails or slugs)	*Angiostrongylus cantonensis*	Reported in Louisiana, Hawaii, the South Pacific, Pacific Islands, Southeast Asia, Asia, Australia, and the Caribbean
Raw vegetables	*Toxoplasma gondii*	Consumption of raw, unwashed vegetables
Unpasteurized milk	*Coxiella burnetii*	Animal exposures (particularly placenta and amniotic fluid)
	Tickborne encephalitis virus	Tick bite or ingestion of unpasteurized milk; endemic to Eastern and Central Europe, East and Southeast Asia
	Listeria monocytogenes	Can be found in about 5% of unpasteurized milk samples and products
	Toxoplasma gondii	Consumption of raw goat milk
SEASON		

Fall	Enteroviruses	Peak incidence in late summer and early fall; enterovirus 71 a cause of large outbreaks in Asia, with children primarily affected
	Arthropod-borne pathogens	Geographically specific agents/risks
Winter	Influenza virus, other respiratory viruses	Sporadic cases in children, with most reports from Japan and Southeast Asia
Spring	Enteroviruses	Peak incidence in late summer and early fall; enterovirus 71 a cause of large outbreaks in Asia, with children primarily affected
	Arthropod-borne pathogens	
Summer	Enteroviruses	Peak incidence in late summer and early fall; enterovirus 71 a cause of large outbreaks in Asia, with children primarily affected
	Naegleria fowleri	Swimming or diving in brackish, freshwater lakes or ponds
	Arthropod-borne pathogens	Geographically specific agents/risks
RECREATION		
Camping or hunting	Arthropod-borne pathogens	Geographically specific agents/risks
Spelunking	Rabies virus	Airborne transmission has been reported rarely in caves inhabited by millions of bats
	Histoplasma capsulatum	Inhalation of spores from soil contaminated with bat guano
Sexual activity	Human immunodeficiency virus	Global risk
	Treponema pallidum	Global risk
	Herpes simplex virus 2 (HSV-2)	HSV-1 also can be transmitted by sexual activity
Water sports	*Naegleria fowleri*	Swimming or diving in brackish, freshwater lakes or ponds
	Leptospira spp.	Exposure to water contaminated with urine of infected animals via swallowing water or skin contact
BLOOD TRANSFUSION OR ORGAN TRANSPLANTATION		
	Toxoplasma gondii	Infection can occur through blood transfusion or organ transplantation
	Rabies virus	Rare case reports of transmission via organ transplantation
	Balamuthia mandrillaris	Rare case reports of transmission via organ transplantation
	Lymphocytic choriomeningitis virus	Rare case reports of transmission via organ transplantation
FOREIGN TRAVEL		
Global	West Nile virus	Geographically specific risks
	Rabies virus	Dog bites are the most common mode of acquisition in developing countries
	HSV-1 and HSV-2	Sporadic
	Influenza	Seasonal by region
	Measles	Measles subacute sclerosing panencephalitis can occur despite history of immunization (child generally had unrecognized infection before measles vaccine)
	Enteroviruses	Seasonal by region

	Human immunodeficiency virus	Sexual activity and bloodborne
	Plasmodium spp.	Tropical and subtropical areas
Africa	Chikungunya virus	Particularly Tanzania
	Poliovirus	Wild poliovirus transmission still occurs in Afghanistan, India, Pakistan, Nigeria
	Histoplasma capsulatum	
	Microfoci throughout Africa	
	Taenia spp.	East Africa, particularly in underdeveloped communities with poor sanitation and where people eat raw or undercooked pork
Asia	Chikungunya virus	Particularly India, Indonesia, Thailand, and Indian Ocean islands
	Japanese encephalitis virus	Including Southeast Asia
	Tickborne encephalitis virus	Central Europe to Japan
	Borrelia burgdorferi	Temperate forested regions throughout northern Asia
	Histoplasma capsulatum	Microfoci throughout eastern Asia
	Gnathostoma spinigerum	Southeast Asia, particularly Thailand, and Japan
	Nipah virus	Southeast Asia, particularly Malaysia
	Taenia spp.	Southeast Asia, particularly in underdeveloped communities with poor sanitation and where people eat raw or undercooked pork
Australia	Murray Valley encephalitis virus	Also in New Guinea
	Japanese encephalitis virus	Northern Australia
	Histoplasma capsulatum	Microfoci throughout Australia
	Hendra virus	Exposure to body fluids and excretions of infected horses is important
Caribbean	Venezuelan equine encephalitis virus	Trinidad
Europe	Tickborne encephalitis virus	Central Europe to Japan
	Chikungunya virus	Italy (northeastern), France (southern)
	Anaplasma phagocytophila	Temperate zones, particularly Germany, Portugal, and Denmark
	Toscana virus	Italy, Mediterranean
	Borrelia burgdorferi	Temperate forested regions throughout Europe, particularly eastern and central Europe
	Taenia spp.	Eastern Europe, particularly in underdeveloped communities with poor sanitation and where people eat raw or undercooked pork
Mediterranean	Toscana virus	Central Italy, France, Spain, Portugal, Greece, Cyprus
North America	Powassan virus	Northeastern and central US, Canada
	California/La Crosse virus	Midwestern and eastern US

	St. Louis encephalitis virus	Geographic range extends from Canada to Argentina, but most human cases in the western US, with periodic outbreaks in central and eastern US
	Ehrlichia chaffeensis	Southern and central US, and mid-Atlantic and coastal states
	Anaplasma phagocytophila	Wooded areas of the north and northeastern US, mid-Atlantic, Midwest, West Coast
	Rickettsia rickettsii	Throughout southern Canada and North America, with peak incidence in southeast and south central US, northern and southwestern Mexico, Costa Rica and Panama
	Eastern equine encephalitis	Highest incidence in Atlantic and Gulf states
	Venezuelan equine encephalitis virus	Florida and southwestern US, rarely in border states (Texas, Arizona); tropical latitudes of Mexico and Central America
	Western equine encephalitis virus	Most cases occur in western US and prairie provinces in Canada, but WEE also occurs in Mexico and Central America; infection associated with residence in rural areas and with agricultural occupations and other outdoor activities that lead to contact with the vector mosquito
	Borrelia burgdorferi	Eastern US, Upper Midwest, and Pacific Northwest; epidemics in summer months when ticks actively seek hosts and human outdoor activity is greatest
	Coccidioides spp.	Semiarid regions of southwestern US and Mexico
	Blastomyces dermatitidis	Southeastern and central states, midwestern states bordering the Great Lakes; thrives in decaying vegetation or wet soil
	Histoplasma capsulatum	Endemic in Mississippi, Ohio and Missouri River valleys in US and other microfoci throughout US, Mexico, and Central America
	Balamuthia mandrillaris	Highest number of cases reported from Arizona, California, and Texas in US; also occurs in Mexico and Central America
	Taenia spp.	Mexico and Central America, especially in underdeveloped communities with poor sanitation and where people eat raw or undercooked pork
	Gnathostoma spinigerum	Mexico and Central America; humans become infected by eating undercooked fish or poultry containing third-stage larvae, or reportedly by drinking water containing infective second-stage larvae
Russia	*Taenia* spp.	More prevalent in underdeveloped communities with poor sanitation and where people eat raw or undercooked pork
	Tickborne encephalitis virus	Eastern Russia
South America	Venezuelan equine encephalitis virus	Tropical latitudes, particularly Colombia, Venezuela, Peru, and Ecuador
	St. Louis encephalitis virus	From Canada to Argentina, but most human cases occur in the US
	Western equine encephalitis virus	Associated with residence in rural areas and with agricultural occupations and other outdoor activities that lead to contact with the vector mosquito
	Rickettsia rickettsii	Brazil and Argentina
	Coccidioides spp.	Semiarid regions

	Histoplasma capsulatum	Microfoci throughout South America
	Gnathostoma spinigerum	Consuming undercooked fish or poultry containing third-stage larvae, or reportedly by drinking water containing infective second-stage larvae
	Bartonella bacilliformis	Middle altitudes of Andes Mountains
	Taenia spp.	More prevalent in underdeveloped communities with poor sanitation and where people eat raw or undercooked pork

Box 44.1

Conditions Mimicking Encephalitis

Immune Mediated

Anti-*N*-methyl-D-aspartate receptor-associated (NMDAR) and other autoimmune encephalitides[a]

Rheumatologic causes (systemic lupus erythematosus, Sjögren syndrome, Behçet disease, sarcoidosis)

Small vessel vasculitis

Corticosteroid-responsive encephalopathy associated with Hashimoto thyroiditis

Acute disseminated encephalomyelitis (ADEM)

Periarteritis nodosa

Toxic Encephalopathy

Bacterial toxins (*Shigella* spp., *Campylobacter jejuni, Salmonella* spp.)

Reye syndrome

Acute toxic ingestion

Lead intoxication

Hyperpyrexic encephalopathy and shock syndrome

Inborn Error of Metabolism

Ornithine transcarbamylase deficiency, heterozygote

Glutaric acidemia type 1

Medium-chain acyl coenzyme A dehydrogenase deficiency

Mitochondrial encephalopathy with lactic acidosis and stroke syndrome

Acute intermittent porphyria

Acquired Metabolic

Electrolyte disturbances

Renal disorder

Liver disorder

Endocrine disorder

Vitamin deficiency

Tumor

Brainstem glioma

Other neoplasms (primary or metastatic; paraneoplastic disease)

Other Central Nervous System Conditions

Stroke

Pseudotumor cerebri

Acute confusional migraine

Brain malformations

Psychosis

Epilepsy

Bacterial meningitis

Brain or parameningeal abscess

Endocarditis complicated by brain embolism

Venous sinus thrombosis

Subdural or epidural hematoma

Head injury

Connective tissue disorder

---

[a] Two broad categories of antigens: (1) intracellular paraneoplastic antigens, including Hu, Ma2, CV2 CRMP5; and (2) cell surface antigens, such as voltage-gated potassium channels and others.

The reported incidence of acute encephalitis varies throughout the world and ranges between 1.5 and 7.4 per 100,000 population.[2–4] Most studies find a higher incidence in the pediatric age group than in adults.[3] Data from hospitalizations in England over a 10-year period show an overall population incidence of 1.5 per 100,000, with rates of 2.8 per 100,000 children and 8.7 per 100,000 infants.[5] Similar rates in children were found in Finland, where the incidence was 8.8 per 100,000 from 1973 to 1987, and in Slovenia, where the incidence was 6.7 per 100,000 from 1979 to 1991.[5,6]

Encephalitis due to vaccine-preventable diseases such as measles, mumps, and rubella has decreased dramatically in the past several decades in the US and in other regions where these vaccines are available. The spectrum of causative agents has changed over time, especially as new pathogens have been discovered, including West Nile virus, Nipah virus, enteroviruses (EVs) 71 and D68, *Balamuthia mandrillaris, Baylisascaris procyonis,* and Chandipura virus.[6–8]

Viruses

Enteroviruses

EVs, nonenveloped RNA picornaviruses, cause approximately 10 to 15 million symptomatic infections per year in the US.[9] EVs are common causes of aseptic meningitis. Encephalitis is a rare complication of EV infection, but because EV infections are ubiquitous, they are a leading cause of encephalitis in children and are responsible for 10% to 15% of encephalitis cases for which an etiology is identified.[10] In the late 1990s, outbreaks of EV-71 in Asia associated with hand-foot-and-mouth disease in young children were noted along with neurologic complications.[11,12]

An emerging issue involving EV-D68, an enterovirus typically associated with respiratory symptoms, has been putatively associated with encephalitis and acute flaccid myelitis (AFM).[13] A widespread respiratory outbreak of EV-D68 in the Midwest in 2014 was temporally associated with cases of AFM.[14] Phylogenetic analysis of a subset of cases showed that they all grouped into a clade B1 virus, further strengthening the putative association between EV-D68 and AFM.[15]

Human Parechoviruses

The reclassification of former enteroviruses, echovirus 21 and echovirus 22, was the genesis of the new human parechovirus (HPeV) genus. Echoviruses 21 and 22 now are classified as HPeV-1 and HPeV-2 respectively. At least 16 HPeV serotypes have been described to date; many have been associated with encephalitis, most often in children <2 years of age.[16] The relative frequency of HPeV encephalitis is unknown. Encephalitis due to HPeV would have been missed in the past because polymerase chain reaction (PCR) testing for EVs does not detect HPeVs.

Herpesviruses

Herpesviruses are a large group of enveloped DNA viruses, and at least 8 herpesvirus types are known to infect humans. Similar to EVs, herpesviruses are a frequent cause of human disease. Herpes simplex virus 1 (HSV-1) is the most commonly identified cause of sporadic encephalitis in adults and follows EV as the most commonly identified cause of encephalitis in children.[17,18] The worldwide incidence of HSE is approximately 500,000 persons per year, and 30% to 50% are <20 years of age. Outside of the neonatal period, most cases of herpes simplex encephalitis (HSE) in children are a consequence of primary HSV-1 infection, whereas most HSE cases in adults are the result of HSV-1 reactivation. In a cohort of

322 pediatric encephalitis cases over a 12-year period at a single tertiary care facility in Canada, 5% were due to HSE.[19]

Other herpesviruses can cause encephalitis. Varicella-zoster virus (VZV), previously a significant cause of encephalitis, became uncommon among pediatric patients after the introduction of universal vaccination.[20]

Primary varicella infection can be complicated by pure cerebellar ataxia, meningoencephalitis, or acute disseminated encephalomyelitis (ADEM), with the median time to development of neurologic symptoms 5 days after onset of rash.[21] However, neurologic manifestations may predate the onset of cutaneous findings or, in some cases, can be present in the absence of rash, complicating recognition of this infection.

The diagnosis of Epstein-Barr virus (EBV) encephalitis is challenging because after acute infection, the virus remains latent in lymphocytes and can reactivate in various settings. Detection of EBV in cerebrospinal fluid (CSF) therefore is not necessarily diagnostic of EBV encephalitis and, alternatively, lack of CSF EBV detection does not rule it out. In a cohort of pediatric patients with encephalitis, microbiologic evidence of EBV infection was identified in 6% of cases, but only 1 of 21 children had a clinical presentation suggestive of infectious mononucleosis.[22] Distinctive presentations of EBV CNS infection include pure cerebellar ataxia and “Alice in Wonderland” syndrome, characterized by metamorphopsia.[23,24]

The role of human herpesvirus 6 (HHV-6) in encephalitis in the immunocompetent host is controversial. Interpretation of CSF PCR results is problematic because once infected, the virus results in a lifelong latent infection in humans. Additionally, HHV-6 DNA is covalently integrated into the cell chromosomes in about 1% of the general population. Both situations lead to false-positive HHV-6 PCR results in CSF.[25] Nevertheless, HHV-6 likely is responsible for some portion of encephalitis in immunocompetent hosts, particularly in children <2 years experiencing a primary infection.[26] Other herpesvirus infections are rare in immunocompetent children.

Arboviruses

Arboviruses are viruses transmitted by an arthropod vector and are well-recognized causes of encephalitis. Three arbovirus families are known to cause encephalitis in humans: Togaviridae, Flaviviridae, and Bunyaviridae. Of these families, the viruses responsible for most clinically significant disease in the US include eastern equine encephalitis (EEE) virus and western equine encephalitis (WEE) virus (Togaviridae family); West Nile virus (WNV), St. Louis encephalitis virus, Powassan virus (Flaviviridae family); and La Crosse virus (LACV) from the California serogroup (Bunyaviridae family).

WNV was detected for the first time in the Western hemisphere in 1999 and currently is the leading cause of arboviral encephalitis in the US.[27] From 2003 to 2012, 13,108 cases of WNV were reported in the US, but only 505 (4%) of all reported cases of West Nile neuroinvasive disease (WNND), which includes encephalitis, aseptic meningitis, and acute flaccid paralysis, were in children.[28] The Centers for Disease Control and Prevention (CDC) report a WNND incidence of 0.68 cases per million children compared with 5.35 cases per million adults from 2003 to 2012.[28] Of the pediatric patients, the median age was 12 years.

LACV is the second most common cause of arboviral infections in the US but is the most common cause of neuroinvasive arboviral disease in children.[28] Over a 10-year period from 2003 to 2012, 754 cases of LACV were reported; 665 (88%) were in children <18 years, with median age of 7 years.[28] In contrast to WNV, infection with LACV occurs in specific geographic areas, primarily in the Appalachian and midwestern regions. Powassan virus, an emerging tickborne arbovirus in the northeastern US and Canada, is rarely identified in children, with only 8 pediatric cases identified in the US between 2003 and 2012.[28] A number of arboviruses are important outside the US (see Table 44.1). In hyperendemic areas, Japanese encephalitis virus causes several thousand cases annually, primarily in children in Asia, southern Asia east of Pakistan, and Southeast Asia.[29] Chikungunya virus is an arbovirus first discovered in Tanzania in 1952, with most illnesses characterized by fever, rash, and polyarthralgia. In the past decade, explosive outbreaks of chikungunya have occurred in several areas of the world, including Africa, Asia, Europe, the Indian and Pacific Oceans, the Americas, and the Caribbean. Neurologic illnesses, including encephalitis, have been associated with some cases. Zika virus has also resulted in explosive outbreaks and seems to have particular neurologic virulence. A few case reports of encephalitis have been linked to Zika virus, but more importantly, it has been shown to cause microcephaly in the fetus.

Other Viruses

Other less frequent but important viral causes of encephalitis include lymphocytic choriomeningitis (LCM) virus and rabies virus. LCM is an arenavirus acquired from infected house mice, hamsters, and guinea pigs. Infections occur when feces, saliva, or urine from LCM-infected rodents are inhaled or ingested. Infections are reported more frequently in winter months when rodents typically migrate indoors.[30] The incidence of LCM is unknown, but it is likely that infections go unrecognized.

Rabies is rare in the US, but 25,000 to 61,000 deaths are estimated to occur annually worldwide, primarily from contact with rabid dogs.[31] These cases occur mostly in Asia, Africa, and Latin America, where animal rabies control and postexposure prophylaxis are limited. Rabies is unique among encephalitis viruses; the incubation period generally is between 20 and 60 days but can range from a few days to 6.5 years.[32] In the US, 43 rabies cases were recognized between 1995 and 2009; 10 cases were imported (usually a canine strain), and the remaining cases were acquired in the US. Most US cases were related to bat exposures, and often the bite event was unrecognized. Bats have very small teeth and, therefore, bites may not be noticed and marks not visible (Fig. 44.1).

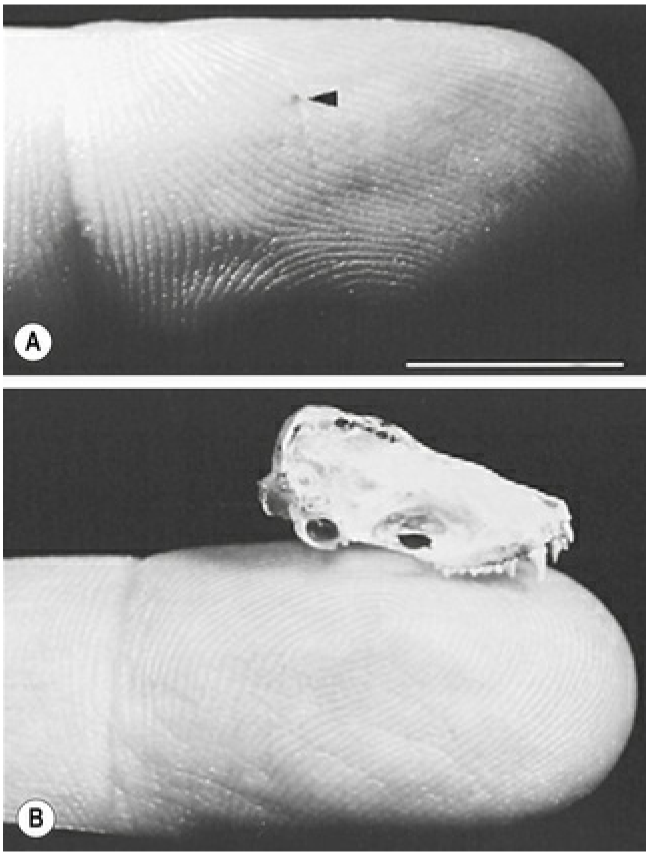

FIGURE 44.1 Puncture wound of a bite from a silver-haired bat (A) and skull of silver-haired bat (B). (Reprinted from Jackson AC, Fenton MB. Human rabies and bat bites. Lancet 2001;357:1714.)

Influenza-associated encephalitis and encephalopathy have been described sporadically in children and follow seasonal influenza patterns during winter months in temperate climates. Most influenza-associated encephalitis cases, especially acute necrotizing encephalopathy (ANE), are reported from Japan,[33] but cases of encephalitis and encephalopathy occur throughout the world, including the US.[34] Neurologic complications may be particularly prominent with specific strains of influenza, such as the 2009 pandemic influenza A virus H1N1.[35]

Other viruses important outside the US include measles, Nipah virus, and arboviruses. There are an estimated 30 million cases of measles worldwide annually, and acute encephalitis occurs in 1 of 1000 cases. Subacute sclerosing panencephalitis (SSPE) is an indolent, progressive, and fatal form of measles encephalitis that typically becomes manifest several years after infection. Because measles vaccination is universal in the US and many other countries, a history of vaccination is common in patients with SSPE.

These SSPE cases likely represent an unrecognized infection acquired before immunization.[36] This is supported by genetic analysis of virus from brain specimens where wild-type measles virus is identified rather than vaccine type virus.[37]

Emerging zoonotic viruses associated with encephalitis include Nipah, Hendra, and bornavirus. Nipah virus is a paramyxovirus first identified as a cause of epidemic encephalitis in pig farmers in Malaysia in 1999,[38] and later in Singapore,[39] Australia,[40] Bangladesh,[41,42] and India.[42] Hendra virus is another paramyxovirus originally reported in Australia among people with contact with horses, although the natural reservoir likely is bats.[43] A newly described bornavirus has been linked to three human encephalitis cases in adults in Germany, all with squirrel contact.[44]

Bacteria

Important bacterial causes of encephalitis include *Rickettsia rickettsii*, *Borrelia* species, *Bartonella henselae* (and other *Bartonella* species), *Anaplasma phagocytophila, Ehrlichia* spp., and *Mycobacterium tuberculosis*. Importantly, meningitis due to *Neisseria meningitidis* and *Streptococcus pneumoniae* can cause clinical manifestations that are indistinguishable from encephalitis.

Bacterial tickborne diseases follow a seasonal pattern. Rocky Mountain spotted fever (RMSF), caused by infection with *R. rickettsii*, occurs during the spring, summer, and fall months when ticks are most active and when there is an increase in human outdoor recreational activity. Although the vector tick for RMSF is widespread throughout the US, the tick associated with Lyme disease is endemic to the eastern and upper midwestern states, and Lyme neuroborreliosis is most commonly found in patients with residence in or travel to these regions. Neuroborreliosis typically follows acute infection with *Borrelia burgdorferi* by 3 to 10 weeks and thus can manifest in cooler months. *B. henselae* (and other *Bartonella* spp.), the agent of cat-scratch disease, is associated with encephalopathy in approximately 15% of cases.[45] Cat-scratch encephalopathy occurs most commonly in children and is characterized by seizures and often status epilepticus.

Fungi

Fungal central nervous system (CNS) disease generally manifests as meningitis and brain abscesses, but some patients have encephalitis-like symptoms. Fungal CNS infection typically is subacute or chronic, in contrast to the more acute presentations of viral or bacterial encephalitis. Important fungal causes in the US include *Coccidioides* spp., *Cryptococcus* spp., *Histoplasma capsulatum,* and *Blastomyces dermatitidis* (see Table 44.1 for endemic areas). *Cryptococcus gattii* has emerged recently in the Pacific Northwest and has a greater propensity to cause illness in immunocompetent hosts than *Cryptococcus neoformans*.[46]

Free-Living Amebas and Parasites

Encephalitis due to free-living amebas can be divided into two clinical entities: (1) primary amebic meningoencephalitis, a fulminant infection occurring in children and young adults due to *Naegleria fowleri* (also known as "the brain-eating ameba") and (2) granulomatous amebic encephalitis, typically caused by infection with *Acanthamoeba* spp. or *Balamuthia mandrillaris.* These three pathogens are widely dispersed in soil and water. *N. fowleri* infects immunocompetent hosts, *Acanthamoeba* spp. chiefly causes infections in immunocompromised hosts, and *B. mandrillaris* infections are described in both host groups. The importance of *Balamuthia* as a causative agent of encephalitis is increasingly recognized.[47]

Significant protozoan parasites associated with encephalitis include *Toxoplasma gondii* and *Plasmodium falciparum*. *T. gondii* typically is acquired through foodborne contact or through direct contact with cat feces containing oocysts.[48] Most cases of *P. falciparum* malaria in the US are imported in people returning from endemic areas in Africa, Asia, and the Americas.[49]

B. procyonis, the common raccoon roundworm, is an important cause of eosinophilic encephalitis, especially in the US.[50] Other important neurotropic helminths include *Gnathostoma spinigerum* and *Angiogstrongylus* spp. *G. spinigerum* is endemic in Southeast Asia and is being recognized increasingly in Central and South America.[51,52] *Angiostrongylus* spp. have been reported in the South Pacific, Asia, Australia, and the Caribbean and in the US in Louisiana and Hawaii. Notably, Hawaii is experiencing an upsurge of cases.[53,54]

Other Causes

Hundreds of additional infectious agents have been associated with encephalitis, but the relevance and frequency of many are unknown. In particular, when a nonneurotropic agent is identified in a patient with encephalitis, particularly when identified only outside the CNS, causality is uncertain. For example, several large case series have identified *Mycoplasma pneumoniae* as one of the most commonly diagnosed infections among children with encephalitis.[54,55] However, *M. pneumoniae* is a ubiquitous pathogen, and up to 80% of the human population have evidence of past exposure. Even when immunoglobulin M antibody to *M. pneumoniae* is identified in a patient, the significance of the finding is unclear given the high background incidence of acute infection and the limitations of serologic testing.[56,57] With similar uncertainty, adenovirus, parvovirus B19, rotavirus, and human metapneumovirus have been implicated in encephalitis.[58–61]

Common noninfectious illnesses can mimic infectious encephalitis, including neoplasms, vasculitis, stroke, drug reactions, paraneoplastic syndromes, and autoimmune disease (see Box 44.1). Immune-mediated encephalitis, anti-*N*-methyl-D-aspartate receptor (NMDAR) encephalitis, is recognized increasingly as a relatively frequent cause of encephalitis syndrome.[62] Initially, the syndrome was described in young women with ovarian teratomas who came to attention with acute psychosis and personality changes that progressed to decreased level of consciousness, dyskinesia, autonomic instability, and hypoventilation.[62] Movement disorders, seizures, and psychiatric symptoms are described commonly in affected individuals. As awareness increases, there are a striking number of cases of anti-NMDAR encephalitis identified in children and young adults.[63] Unlike adult patients, pediatric patients are less likely to have a tumor identified.[64] Viral encephalitis also may trigger anti-NMDAR and other autoimmune encephalitides.[65]

Pathogenesis

The pathogenesis of acute viral encephalitis is not well understood and is highly variable depending on the causative agent. Enteroviruses, HPeVs, HSV-1, arboviruses, and rabies are examples of neurotropic viruses in which the virus directly infects neuronal tissue. Measles, EBV, and rubella are examples of viruses that can trigger an autoimmune reaction with a resultant postinfectious encephalitis, ADEM, in which the white matter of the brain is involved predominantly (discussed in Chapter 45). Encephalitis symptoms in bacterial meningitis and rickettsial infections, on the other hand, are caused by the vasculitis and inflammation of the surrounding infection. Inflammatory response to bacteria, fungi, and parasites especially can lead to hydrocephalus.

Infectious agents can enter the CNS through diverse pathways. The most common route of invasion is through the bloodstream, as is the case for EVs, HPeVs, and arboviruses as well as for most bacteria, rickettsia, and fungal agents. The bloodborne agent penetrates the blood-brain barrier through the choroid plexus or through vascular endothelium.[66] An intraneuronal route is used by some viruses, such as rabies and HSV-1. HSV-1 can cause encephalitis during the primary infection or reactivation of the latent virus.

When inside the CNS, the offending pathogen may target only certain cells, and, depending on the region involved, variable clinical manifestations develop. Cortical infection or reactive parenchymal swelling can lead to an altered level of consciousness, a ubiquitous clinical sign in encephalitis. Agents with specific predilection to areas such as the brainstem can progress rapidly to coma or respiratory failure. Arboviruses primarily affect the cortical grey matter, brainstem, and thalamic nuclei. HSE is characterized by hemorrhagic and necrotizing lesions characteristically located in the temporal lobes, orbital frontal lobe cortex, and limbic structures.[67]

Typical histology in viral encephalitis includes perivascular mononuclear cell inflammation, phagocytosis of neurons, and microglial nodules. Certain viruses have distinctive histopathologic features, such as intranuclear inclusions with herpesviruses, and Negri bodies pathognomonic for rabies.

For some organisms, such as influenza and *B. henselae*, mechanisms causing neurologic signs and symptoms are not always well understood. In these cases, there is definitive evidence of recent infection, but the pathogen generally is not found in the brain or CSF. In many influenza-associated encephalopathy cases, there is bilateral symmetric edema and apoptosis of neurons in the absence of pleocytosis, suggesting a different pathogenesis, such as that mediated by cytokines.

Rickettsial agents generally cause endovascular infections, with CNS manifestations related to a small vessel vasculitis. Subsequent meningeal irritation with perivascular mononuclear infiltrates develops. Characteristic CNS pathologic lesions include multifocal glial nodules and arteriolar microinfarctions.[68] In tuberculous, fungal, or partially treated bacterial meningitis, subarachnoid exudate from chronic basilar meningeal inflammation leads to obstruction of CSF reabsorption with resultant communicating hydrocephalus and cranial nerve palsies. Vasculitis of intraparenchymal vessels leads to infarcts and focal neurologic deficits.

N. fowleri causes hemorrhagic destruction of grey matter and devastation of the olfactory bulbs.[69] The hallmark of *B. mandrillaris and Acanthamoeba* infections is granulomatous amebic encephalitis characterized by multinucleated giant cells, focal necrosis, and hemorrhage. The pathology of *B. procyonis* is characterized by CNS larval migration with histology demonstrating inflammation and necrosis with track-like spaces, as well as abundant eosinophils.[70]

Clinical Manifestations and Differential Diagnosis

The clinical manifestations of encephalitis are extremely variable and reflect the specific area and degree of brain involvement and inherent pathogenicity of the offending agent (Table 44.2). Clinical criteria for the diagnosis of encephalitis have been established (Box 44.2).[1] The hallmark of encephalitis is altered level of consciousness lasting more than 24 hours, not attributable to an alternative cause. Other clinical findings can include fever, seizures, impaired cognition, behavioral changes, speech disturbances, hemiparesis, cranial neuropathies, and other focal neurologic signs. Physical findings outside the CNS can provide important clues to etiology. For example, a petechial skin eruption is suggestive of RMSF, whereas regional lymphadenopathy may indicate bartonellosis.

TABLE 44.2

Associated Manifestations for Specific Agents in Encephalitis

Clinical Features	**Agents**
Subacute or chronic neurologic symptom	*Acanthamoeba* spp. *Balamuthia mandrillaris* *Coccidioides* spp.
	Cryptococcus neoformans
	Histoplasma capsulatum Measles (subacute sclerosing panencephalitis) *Mycobacterium tuberculosis* *Tropheryma whipplei*
Hepatitis	*Coxiella burnetii*
Hepatosplenomegaly	*Histoplasma capsulatum*
Hydrophobia	Rabies virus
Lymphadenopathy	*Bartonella henselae*
	Cytomegalovirus[a]
	Epstein-Barr virus
	Human immunodeficiency virus
	Mycobacterium tuberculosis
	Toxoplasma gondii[a]
	West Nile virus
Parotitis	Human immunodeficiency virus
	Mumps virus Lymphocytic choriomeningitis virus
	Parainfluenza virus
Respiratory symptoms	Adenovirus
	Histoplasma capsulatum
	Influenza virus
	Mycoplasma pneumoniae
	Mycobacterium tuberculosis
	Parainfluenza virus
Retinitis/chorioretinitis	*Bartonella henselae*
	Cytomegalovirus[a]
	Histoplasma capsulatum *Mycobacterium tuberculosis* *Toxoplasma gondii*[a]
	Treponema pallidum
	West Nile virus
Exanthems	
Hand-foot-and-mouth disease	Enterovirus
Macules/papules on trunk	West Nile virus
Petechiae	*Rickettsia rickettsii* (and other rickettsia)
Recent macular exanthem	Human herpesvirus 6
Salmon-colored macules/papules	Rubella virus
Vesicles	Herpes B virus
	Varicella-zoster virus
Neurologic Features	
Ataxia	Epstein-Barr virus

	Listeria monocytogenes
	Mycoplasma pneumoniae
	Varicella-zoster virus
Change in taste or smell	*Naegleria fowleri* Herpes simple virus type 1 (anosmia)
Cranial nerve palsies	*Balamuthia mandrillaris*
	Borrelia burgdorferi
	Coccidioides spp.
	Epstein-Barr virus
	Histoplasma capsulatum
	Mycobacterium tuberculosis
	Naegleria fowleri
	Toxoplasma gondii[a] Syphilis
Paralysis[b]	Enteroviruses (71, D68)
	Japanese encephalitis virus
	La Crosse virus
	Tickborne encephalitis virus
	West Nile virus
Psychiatric abnormalities	Herpes simplex virus 1 Anti-NMDAR encephalitis Rabies
Myoclonus/jerks	Measles virus (SSPE)
	Nipah virus
Sensorineural hearing loss	Mumps virus
Visual loss	JC virus (progressive multifocal leukoencephalopathy)[a]
	Baylisascaris procyonis
Laboratory Features	
Cerebrospinal fluid (CSF) atypical lymphocytes	Cytomegalovirus[a]
	Epstein-Barr virus
	West Nile virus
CSF eosinophils (can be mistaken for neutrophils in CSF; Wright or Giemsa stain is needed to identify eosinophils)	*Angiostrongylus* spp. *Baylisascaris procyonis* *Coccidioides* spp.
Morulae in white blood cells	*Anaplasma phagocytophila*
	Ehrlichia spp.
CSF lymphocytosis with hypoglycorrhachia	*Mycobacterium tuberculosis* *Balamuthia mandrillaris* *Coccidiodes* spp.
Neuroimaging Abnormality	
Acute necrotizing encephalopathy (ANE)	Influenza virus (and other respiratory viruses)
Arteritis/infarctions	*Rickettsia* spp.
	Treponema pallidum
	Varicella-zoster virus
Basal ganglia	Influenza virus (ANE)
	Enteroviruses
	Epstein-Barr virus West Nile virus and other arboviruses (Japanese encephalitis)
Brainstem	Enteroviruses
	Epstein-Barr virus
	Herpes simplex virus 1

	Influenza virus (ANE)
	Listeria monocytogenes
	Mycobacterium tuberculosis
	West Nile virus
Calcifications (neonate)	Cytomegalovirus
	Lymphocytic choriomeningitis virus
	Toxoplasma gondii
Cerebellar	Epstein-Barr virus
	Mycoplasma pneumoniae
	Varicella-zoster virus
	West Nile virus
Corpus callosum	West Nile virus
Frontal lobe	Enteroviruses
	Herpes simplex virus 1
	Herpes simplex virus 2
	Treponema pallidum
Hydrocephalus	*Balamuthia mandrillaris*
	Coccidioides immitis
	Histoplasma capsulatum
	Mycobacterium tuberculosis
	Toxoplasma gondii (neonate)[a]
Microcephaly	Cytomegalovirus[a]
	Lymphocytic choriomeningitis virus
	Toxoplasma gondii (neonate)[a] Zika virus
Myeloencephalitis	*Gnathostoma* spp.
Parietal lobe	West Nile virus
Space-occupying lesions	*Acanthamoeba* spp. *Balamuthia mandrillaris* *Mycobacterium tuberculosis*
	Toxoplasma gondii[a]
Temporal lobe	Enteroviruses
	Herpes simplex virus 1
	La Crosse virus
	Treponema pallidum
Thalamus	Enteroviruses
	Epstein-Barr virus
	Influenza virus (ANE)
White matter (different from ADEM)	*Balamuthia mandrillaris*
	Baylisascaris procyonis
	HPeV-3 (especially neonate)
	Human immunodeficiency virus
	JC virus[a]
	Measles virus (SSPE)
	West Nile virus
Electroencephalogram Abnormality	
Periodic lateralizing epileptiform discharges	Herpes simplex virus 1
	Epstein-Barr virus
	La Crosse virus
	Measles virus (SSPE)

[a] Causes encephalitis primarily in immunocompromised patients or the neonate or both.

[b] Testing should be performed on serum at acute phase of disease and then later when sera in acute and convalescent phase of disease are available.

SSPE, subacute sclerosing panencephalitis.

Box 44.2

Diagnostic Criteria for Encephalitis and Encephalopathy of Presumed Infectious or Autoimmune Etiology

Major Criterion (Required)

Altered mental status (defined as decreased or altered level of consciousness, lethargy, or personality change) lasting >24 hours with no identifiable alternative cause

Minor Criteria (2 Required for Possible Encephalitis; ≥3 Required for Probable or Confirmed[a] Encephalitis)

Documented fever ≧38°C (≥100.4°F) within the 72 hours before or after presentation

Generalized or partial seizures not fully attributable to a preexisting seizure disorder

New onset of focal neurologic findings

CSF WBC count ≧5/mm

Abnormality of brain parenchyma on neuroimaging suggestive of encephalitis that is either new from prior studies or appears acute in onset

Abnormality on electroencephalography that is consistent with encephalitis and not attributable to another cause

---

[a] Confirmed encephalitis requires one of the following: (1) pathologic confirmation of brain inflammation consistent with encephalitis; (2) defined pathologic, microbiologic, or serologic evidence of acute infection with a microorganism strongly associated with encephalitis from an appropriate clinical specimen; or (3) laboratory evidence of an autoimmune condition strongly associated with encephalitis.

Adapted from Venkatesan A, Tunkel AR, Bloch KC, et al. Case definitions, diagnostic algorithms, and priorities in encephalitis: consensus statement of the International Encephalitis Consortium. Clin Infect Dis 2013;57:1114–1128.

The characteristic presentation of EV encephalitis is a generalized syndrome, with nonspecific alterations in consciousness ranging from lethargy and mild disorientation to coma. Some strains, such as EV-71 and coxsackievirus A16, cause localized inflammation; clinical symptoms correspond to the specific neurologic area involved. In a Taiwanese epidemic of EV-71, nearly 90% of cases had a biphasic illness where either hand-foot-and-mouth disease or herpangina preceded the onset of myoclonus, tremor, or ataxia.[71] Of hospitalized patients, brainstem encephalitis was a common feature and the case fatality rate was 14%.

Focal CNS involvement is typical of HSE. The classical presentation in adults includes fever, altered level of consciousness, dysphasia or aphasia, focal motor seizures, and hemiparesis, with imaging showing involvement of one or both temporal lobes. Children, however, are more likely to have atypical manifestations. In one study, 25% of children with HSE had atypical features of ataxia, decreased visual acuity, or generalized tonic-clonic seizures.[19] In a large cohort study of children with HSE, more than 50% had neuroimaging evidence of infection outside of the temporal lobes.[72]

Several clinical findings may be suggestive of other herpes group encephalitides. Encephalitis associated with primary varicella infection can manifest as either a nonspecific syndrome or as acute or postinfectious CNS disease, or it may be associated with isolated symptoms of cerebellar ataxia acutely or of ischemic stroke within 6 months after chickenpox.[73,74] Recognition of VZV encephalitis is complicated when neurologic symptoms predate or occur in the absence of skin lesions.[75] Symptoms of EBV encephalitis can include distinguishing features such as “Alice in Wonderland” syndrome (micropsia, macropsia, and/or size distortion of other sensory modalities) or, like VZV, isolated cerebellar ataxia or stroke.[76] HHV-6 infection typically causes a limbic encephalitis, or in the immunocompromised host it can present with multifocal areas of demyelination.[77,78]

Most children with WNV infection are asymptomatic or have a mild febrile illness. Clinical manifestations of West Nile encephalitis

(WNE) include fever, headache, seizures, confusion, paralysis, tremors, facial palsy, photophobia, ataxia, and dysphasia. Acute flaccid paralysis causing a polio-like syndrome is a characteristic finding.[79] Additional manifestations can include hepatitis, myocarditis, pancreatitis, cardiac dysrhythmia, rhabdomyolysis, orchitis, uveitis, and vitritis. Brainstem encephalitis, seizures, movement disorders, cranial neuropathies, cerebellitis, and optic neuritis also are described accompanying features of WNE.[80] Clinical manifestations of LACV are typically nonspecific, with seizures, increased intracranial pressure, focal neurologic signs, and cerebral herniation all reported. Rarely, LACV encephalitis can mimic HSE.[81]

Rabies always should be considered in patients with rapidly progressive encephalitis. Paresthesia at or near the site of bite is a unique feature of rabies. A small percentage of patients with rabies come to attention with the "paralytic" form, with ascending paralysis followed by confusion and then coma. The "furious" form of rabies is more common and is characterized by agitation, hydrophobia, delirium, and seizures.

Neurologic findings of influenza-associated encephalitis typically occur several days after the onset of upper respiratory tract symptoms.[82] One of most serious presentations is ANE.[83–85] Diagnostic criteria for ANE include acute-onset encephalopathy with seizures, absence of CSF pleocytosis, normal blood ammonia levels, and exclusion of an alternative etiology (Box 44.3). Neuroimaging is characterized by symmetric multifocal brain lesions involving the thalamus, internal capsule, cerebellum, and sometimes brainstem (Fig. 44.2).[85] Most cases of ANE occur in previously healthy children <5 years of age, many of whom are of Asian descent, and mortality approaches 30%.[85]

Box 44.3

Clinical Characteristics of Acute Necrotizing Encephalopathy

Clinical

Typical age <5 years, rarely >10 years

Neurologic symptoms onset *during* the peak of febrile illness

Rapid development of encephalopathy, often with seizures

Variable elevation of serum aminotransferases, normal blood ammonia

Normal CSF (increased pressure, or mildly elevated protein level)

Exclusion of other causes (e.g., hypoxia, intoxication, HUS, metabolic disorder)

Cranial Mri

Diffuse, bilateral, symmetric high-intensity signal on T2-weighted images

Unremarkable T1-weighted images

Involvement of periventricular and deep white matter (thalamus, brainstem tegmentum, cerebellum, medulla)

No enhancement with gadolinium

Associated Conditions

Disseminated intravascular coagulopathy/SIRS that *follows* CNS signs

Multiorgan failure that *follows* CNS signs

Autopsy Findings

Edema, apoptosis/necrosis of neurons

No vasculitis

No inflammation

CSF, cerebrospinal fluid; HUS, hemolytic uremic syndrome, MRI, magnetic resonance imaging; SIRS, systemic inflammatory response syndrome.

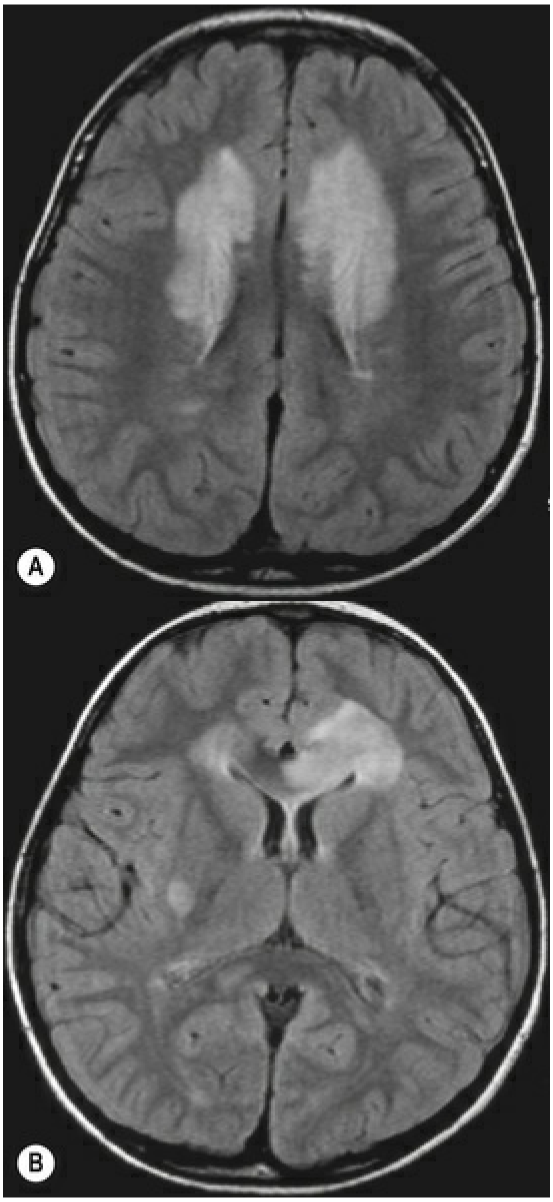

FIGURE 44.2 Acute necrotizing encephalopathy in a 3-year-old with influenza B Sichuan group/Shanghai-like. On the third day of fever and flu-like symptoms, he had acute onset of diminished arousal and recognition, mutism, ataxia, and left-sided increase in tone and reflexes. Axial fluid-attenuated inversion recovery magnetic resonance imaging shows bilateral symmetric, extensive hyperintense lesions in the centrum semiovale with periventricular involvement (A) and in the white matter anterior to the frontal horns, in the corpus callosum, and right globus pallidus (B). (Courtesy of E. N. Faerber and S. S. Long, St. Christopher's Hospital for Children, Philadelphia.)

The clinical descriptions of *M. pneumoniae*–associated encephalitis include a wide variety of neurologic (e.g., lethargy, seizures, hallucinations, and focal neurologic findings) and extraneurologic (e.g., respiratory and gastrointestinal) symptoms. Severity of illness is extremely variable.[56,86] Fungal and *M. tuberculosis* infections of the CNS generally manifest with subacute meningitis. However, acute fulminant presentations with encephalitis-like features have been described.[87]

The clinical manifestations of parasitic infections are highly variable depending on the etiologic agent. For *N. fowleri*, patients typically have headache, nausea, vomiting, and nuchal rigidity, which rapidly progresses to irreversible coma. Individuals also may experience a change in taste or smell. *B. mandrillaris* and *Acanthamoeba* spp. have a less fulminant course characterized by fever, headache, vomiting, ataxia, hemiparesis, tonic-clonic seizures, cranial nerve palsies (particularly third and sixth cranial nerves), and diplopia.[47,88,89] Neuroimaging in patients with *B. mandrillaris* is invariably abnormal, with meningeal enhancement, edema, hydrocephalus, or ring-enhancing lesions[47,90] (Fig. 44.3). Patients with CNS complications of *B. procyonis* have clinical manifestations similar to other encephalitides but also can have ocular disease and CSF eosinophilic pleocytosis; neuroimaging often shows diffuse periventricular white matter changes[91] (Fig. 44.4).

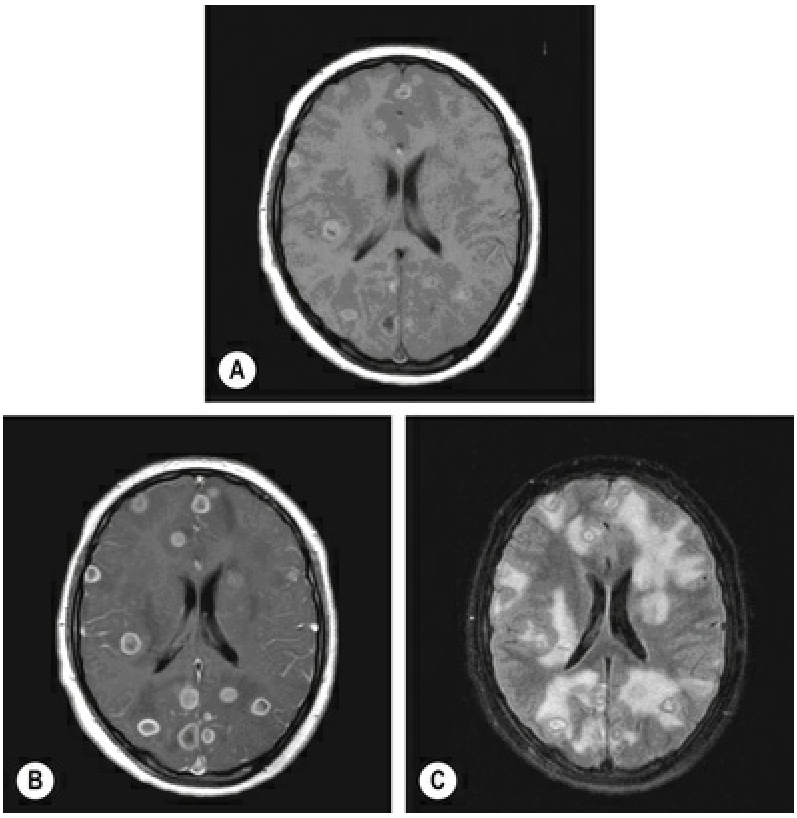

FIGURE 44.3 Magnetic resonance imaging of a patient with widely disseminated amebic encephalitis from *Balamuthia mandrillaris* (1.5-Tesla scanner) using axial T1 (precontrast [A] and postcontrast [B]) and fluid-attenuated inversion recovery (FLAIR) sequences (C). Images demonstrate numerous ring-enhancing lesions seen within the cerebral cortex, subcortical white matter, and deep grey matter, including the thalami and basal ganglia. The T2 hyperintensity seen on the FLAIR images is consistent with perilesional edema and contributes to the lesions having mild local mass effect. (Courtesy of D. Michelson, Loma Linda University School of Medicine, Loma Linda, CA.)

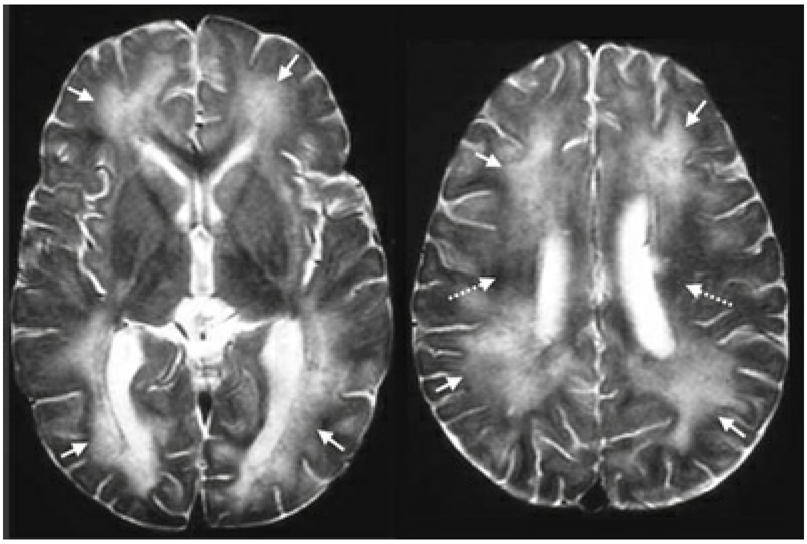

FIGURE 44.4 Magnetic resonance images of a 13-month-old boy with *Baylisascaris procyonis* encephalitis, showing abnormally high signal throughout the central white matter compared with darker signal expected for age. (Courtesy of Sorvillo F, Ash LR, Berlin OGW, et al. *Baylisascaris procyonis:* an emerging helminthic zoonosis. Emerg Infect Dis 2002;8:355–359.)

Noninfectious entities that can mimic encephalitis may have suggestive clinical features. Early symptoms of anti-NMDAR encephalitis, for example, include behavioral changes or psychosis, seizures, and involuntary movements. Recognition of this syndrome is important because, despite the severity, improvement can occur with immunosuppressive therapy and removal of tumor if present.[62] Several other disease processes must be considered in the differential diagnosis of acute encephalopathy, including immune-mediated diseases, toxic ingestions, inborn errors of metabolism, acquired metabolic disorders, mass lesions (tumor or abscess), and other CNS conditions (see Box 44.1).

Special Hosts

Neonates

The epidemiology and clinical presentation of agents causing congenital or neonatal encephalitis differ from those of older children (Table 44.3). Identifying infants with CNS infections can be particularly problematic because the clinical features are extremely vague during the early phase of illness. Congenital infection with cytomegalovirus (CMV), VZV, rubella virus, LCM virus, and *T. gondii* can include CNS infection with structural brain damage and neurologic symptoms present at birth. If infection occurs during the first trimester, there is an increased risk for spontaneous abortion.[92] Later in gestation, congenital infection can lead to chorioretinitis, intracranial calcifications, hydrocephalus, microcephaly or macrocephaly, mental retardation, and seizures.

TABLE 44.3

Differential Diagnosis of Encephalitis in the Neonate

Infection or Disorder	Frequency
PERINATAL INFECTION	
Herpes simplex virus	++
Enterovirus[a]	+++
Adenovirus	+++
Group B *Streptococcus*[b]	+
Listeria monocytogenes[b]	+
Citrobacter spp.[b]	+
CONGENITAL INFECTIONS	
Cytomegalovirus	+++

[c] Combined incidence.

+++, most frequent; ++, frequent; +, occasional.

HSV-1 and HSV-2, EV, HPeV, and HIV are acquired primarily in the perinatal period. Meningoencephalitis may be the sole manifestation of HSV infection or can be associated with skin-eye-and-mouth disease or disseminated disease. Neuroimaging can show diffuse (multilobar) involvement rather than temporal lobe predominance; of 29 infants with HSE, bilateral multilobar (8), thalamic (6), internal capsule and corticospinal tract (5), and pontine involvement was seen.[93] Recognition of HSV is particularly important because of beneficial treatment with acyclovir. Before the availability of antiviral therapy, the infant mortality rates associated with disseminated and HSV CNS disease were 85% and 50%, respectively. Presentation of neonatal HSV CNS disease constitutes a spectrum including nonspecific signs and symptoms,[94,95] apnea, lethargy, focal or generalized seizures, and paralysis.

In neonates, a variety of EVs and HPeVs have been associated with serious complications, including encephalitis and death.[96,97] HPeV-3 is noteworthy in the neonatal period because it appears to be a major cause of neonatal encephalitis, possibly 3 times more common than EV.[98] The typical presentation is fever, rash, irritability, seizures, and occasionally hepatitis. Notably, the CSF is normal in most cases (90%), which suggests that the diagnosis of encephalitis could be overlooked easily.[16,98] Further, neuroimaging in HPeV-3 cases often demonstrates distinctive white matter involvement that may be thought erroneously to be hypoxic ischemia injury or periventricular leukomalacia. Unlike periventricular leukomalacia, however, white matter abnormalities in neonatal HPeV-3 involve the subcortical white matter, entire fiber tracts including the corpus callosum, optic radiation, and grey matter regions such as the posterior thalamus.[98]

As outlined in Table 44.3, evaluation of neonates is somewhat unique. Acyclovir should be administered empirically to ill infants with signs compatible with HSV CNS infection and no other likely diagnosis.

Immunocompromised Hosts

In addition to agents that can cause encephalitis in the immunocompetent host, many additional agents must be considered in the immunocompromised host.

Several herpesviruses (CMV, EBV, HHV-6, VZV) can reactivate to cause encephalitis. CMV is particularly problematic in organ transplant recipients and HIV-infected individuals. CMV encephalitis can manifest as diffuse encephalopathy with confusion, disorientation, psychomotor slowing, and cranial nerve palsies and also can cause periventricular encephalitis.[99] HHV-6 encephalitis occurs predominantly in patients after hematopoietic stem cell transplantation.[100] Although HPeV encephalitis is described most commonly in young children, the report of severe myocarditis and encephalitis in an adolescent with hypogammaglobulinemia highlights its role in patients with humoral immunodeficiencies.[101] JC virus typically causes multifocal demyelinating disease, progressing to multifocal leukoencephalopathy, and is seen almost exclusively in patients with AIDS. Although fungal CNS infections are relatively rare, they are recognized increasingly as the immunocompromised population grows. Similarly, the free-living amebas, *Acanthamoeba* spp. and *B. mandrillaris*, also can cause encephalitis in the immunocompromised host.

Clinical Approach

Despite a thorough diagnostic evaluation, a pathogen is identified in less than half of all cases of encephalitis.[102] Even when an infectious etiology is identified, there may be no specific treatment. However, diagnostic testing has an important role in prognosis, potential postexposure prophylaxis of contacts, counseling of patients and families, and public health interventions. Additionally, the identification of a specific agent can lead to discontinuation of unnecessary antimicrobial and antiviral therapies.[1] There are many important caveats to laboratory testing in patients with encephalitis (Table 44.4).

TABLE 44.4

Laboratory Testing with Focus on Pathogens Found in the United States

Agent	Recommended Diagnostic Studies	Caveats
VIRUS		
Adenovirus	• Cerebrospinal fluid (CSF), respiratory, brain tissue for polymerase chain reaction (PCR) or culture	• Pathogen of unknown neurologic potential
Arboviruses	• Serology is the most useful assay for most arboviruses: CSF immunoglobulin M (IgM), serum IgM and	• Acute viremia stage often over by the time of clinical presentation; however, PCR is sometimes positive in very acute specimens • PCR can be helpful in immunocompromised host because of prolonged viremia and

	IgG (paired sera if possible) for specific viruses as suggested by geography: – West Nile virus (WNV) – St. Louis encephalitis (SLE) virus – California serogroup viruses (e.g., La Crosse virus [LACV]) – Eastern equine encephalitis virus (EEE) – Powassan virus (POW) – Western equine encephalitis (WEE) virus	delayed antibody response • Knowledge of geographic and seasonal variation of arboviruses important and can limit unnecessary testing • CSF IgG for specific arbovirus usually not helpful because of blood-brain barrier integrity; CSF blood contamination can cause false-positive results for both IgM and IgG • High rate of serologic cross-reactivity among arbovirus (WNV, SLE, and POW; individual with prior dengue infection will test positive for WNV IgG) • Antibody typically positive early in presentation, but if negative, repeat on later specimen • WNV: predominance of polymorphonuclear cells in CSF can persist beyond the first 24 hr in contrast to other viral encephalitides • WNV: abnormal-appearing reactive lymphocytes including plasma cell-like and Mollaret-like cells • EEE: CSF WBC counts can be very high, with counts up to 4000/mm^3 • POW: testing only available at Centers for Disease Control and Prevention (CDC) and a few state laboratories
Cytomegalovirus (CMV)	• CSF for PCR • Shell vial on urine, saliva (neonate)	• Serology can be problematic especially because of false-positive results • Rare causes of encephalitis in immunocompetent host • Atypical lymphocytes in CSF
Enteroviruses (EV)	• CSF for PCR • Respiratory swab for PCR • Stool for PCR or culture	• PCR on CSF alone can be negative because EV is present only transiently in CSF; test non–central nervous system (CNS) site (respiratory sample PCR, viral stool culture) to increase yield
Epstein-Barr virus (EBV)	• CSF for PCR • Serum for anti-VCA IgM/IgG, anti-EBNA • Serum heterophile antibody	• Both serology (serum) and PCR (CSF) are recommended • False-negative and false-positive results can occur with EBV PCR. False-positive results occur because EBV DNA is found in peripheral blood mononuclear cells • Atypical lymphocytes in CSF or peripheral blood are consistent but not always present
Herpes simplex virus 1 (HSV-1)	• CSF for PCR • CSF for antibody if >1 wk of symptoms • Neonate: – CSF for culture and/or PCR – Nasopharyngeal (NP) swab for culture and/or PCR – Conjunctival swab for culture and/or PCR – Rectal swab for culture and PCR – Skin lesion swab for	• Outside neonatal period, HSV-1 causes most cases of herpes simplex encephalitis (HSE). In neonatal period, most infections are due to HSV-2 • Approximately 5%–10% of HSE patients have a normal CSF in first lumbar puncture (LP), particularly in children. HSV PCR can be negative in first LP. For cases in which HSE is highly suspected (e.g., temporal lobe involvement), a second LP should be performed for CSF PCR and intrathecal HSV antibody testing • Presence of either HSV IgG or IgM antibody can indicate CNS infection; however,

	culture and/or PCR	diminished blood-brain barrier and possible CSF contamination with blood should be considered when interpreting results
Herpes simplex virus 2 (HSV-2)	• CSF for PCR • CSF for antibody if >1 wk of symptoms • Neonate: – CSF culture and/or PCR – NP, conjunctival, rectal swabs for culture and/or PCR – Skin lesion swabs for PCR and culture	• Neonatal period, HSV-2 important cause of HSE. Beyond neonatal period, HSV-2 causes primarily meningitis syndrome but has been associated with encephalitis • Presence of either HSV IgG or IgM antibody can indicate CNS infection; however, blood-brain barrier issues and possible CSF contamination of blood need to be considered when interpreting results
Human herpesvirus 6 (HHV-6)	• CSF for PCR	• Pathogen of unknown neurologic potential • Not all HHV-6 CSF PCR–positive results correlate with disease; when positive, important to consider chromosomal integration or latent infection
Human immunodeficiency virus (HIV)	• p24 antigen and HIV antibody • Plasma and CSF for PCR	
Human metapneumovirus	• Respiratory tract (NP or throat swab) for PCR	• Pathogen of unknown neurologic potential • CSF PCR rarely positive
Influenza A/B virus	• Respiratory secretions for viral culture • Respiratory secretions for viral antigen test • Respiratory secretions for PCR	• Most cases are encephalopathy (vs. encephalitis) • CSF PCR rarely is positive
JC polyomavirus	• CSF for PCR	• A positive result correlates with diagnosis; negative result does not rule it out
Lymphocytic choriomeningitis virus (LCM)	• CSF for LCM IgM/IgG antibody • Serum for LCM IgM/IgG antibody • Neonate: – Serology on both infant and mother	• One of the few viruses that can cause low glucose in CSF
Measles virus—acute	• CSF for measles virus antibodies • CSF for measles virus PCR • Serum IgG/IgM (paired serum samples if possible) • Brain tissue (if available) for measles virus PCR	• Measles PCR and antibody testing (both serum and CSF)
Measles virus—SSPE	• CSF IgG antibodies • Serum IgG antibodies • Brain tissue (if available) PCR	• Because SSPE is result of longstanding infection, measles IgM is negative; IgG levels in CSF and serum very high
Mumps virus	• CSF for culture or PCR • CSF for IgM/IgM antibodies • Serum for IgM/IgG antibodies (paired	• One of few viruses that can cause low glucose in CSF

	serum samples if possible) • Throat swab for PCR	
Parvovirus B19	• Serum for IgM antibody • CSF for PCR	• Pathogen of unknown neurologic potential
Rabies virus	• Antemortem: serum for antibodies – Saliva and CSF for PCR – Nuchal biopsy for PCR and DFA – Brain tissue (if available) for DFA • Postmortem: – Brain tissue for culture; or antigen detection	• Antemortem testing is challenging but possible • Multiple samples and different assays should be performed. Negative tests antemortem do not rule out rabies • Coordinate testing with local and state health department
Respiratory syncytial virus (RSV)	• Respiratory secretions or PCR antigen	• Pathogen of unknown neurologic potential • CSF PCR rarely positive
Rotavirus	• Stool for antigen detection • CSF PCR (CDC)	• Pathogen of unknown neurologic potential • Typically young child with history of diarrhea; mechanism of CNS illness unclear
Rubella virus	• Serum for antibody • CSF for antibodies	• One of few viruses that can cause low glucose in CSF
Varicella-zoster virus (VZV)	• CSF for PCR • CSF for antibody if >1 week of symptoms • Serum for IgM/IgG • Skin lesions for direct fluorescent antibody (DFA) or PCR	• Because some CNS VZV infections are reactivation, IgM not always positive • Positive test on VZV skin lesions does not prove CNS etiology but may be suggestive
West Nile virus	• See earlier entry "Arboviruses"	
FUNGUS		
Coccidioides spp.	• CSF culture (large volume) • CSF for antigen • CSF for antibody • Serum for antigen • Serum for antibody	• Warn laboratory that coccidioidomycosis is being considered if culture ordered • Eosinophils sometimes present in CSF • "EDTA-heat"–treated antigen test reported to increase sensitivity for CSF and serum samples
Histoplasma capsulatum	• CSF for culture (large volume) • CSF, serum, and urine for antigen detection • CSF for antibody • Serum for antibody	• May need to do multiple tests • Isolated CNS disease can be difficult to diagnose because of insensitive assays • "EDTA-heat"–treated antigen test reported to increase sensitivity for CSF and serum samples
Blastomyces dermatitidis	• CSF for culture (large volume) • CSF, serum, urine for antigen detection • CSF for antibody • Serum for antibody	• May need to do multiple tests • "EDTA-heat"–treated antigen test reported to increase sensitivity for CSF and serum samples
FREE-LIVING AMEBAS AND PARASITES		
Naegleria fowleri	• Wet mount of warm CSF • Brain (if available) histopathology	• Demonstration of motile ameba on wet mount • CSF often demonstrates very high WBC (often with neutrophil predominance), high protein (>100 mg/dL), and low glucose (<50

		mg/dL)
Balamuthia mandrillaris	• Serum for antibody • CSF and/or brain for PCR • Brain (if available) histopathology (special stains)	• Serology and PCR available at specialized laboratories • Brain tissue can show necrotic and hemorrhagic meningoencephalitis • CSF often shows high WBC (lymphocyte or neutrophil predominance), high protein (>100 mg/dL), resembling tuberculous meningitis
Acanthamoeba spp.	• Serum for antibody • CSF and/or brain for PCR • Brain (if available) histopathology (special stains)	• Serology and PCR available at specialized laboratories
Baylisascaris procyonis	• CSF for antibody • Serum for antibody	• Serology available in specialized laboratories (Parasitic Disease Branch, CDC) • Eosinophils almost always present in CSF and peripheral blood
Toxoplasma gondii	• Neonatal: serum for IgG, IgM, IgA, IgE antibodies. Older child: serum for IgG, IgM; CSF for PCR	• Serology can be falsely negative; important to test mother and infant • Often reactivation of disease, so IgM may not be positive, IgG titers persistently high
BACTERIA		
Bartonella henselae	• Serum for indirect fluorescent antibody • Lymph node for PCR	• CSF PCR often negative
Borrelia burgdorferi	• Serum for antibodies sequential (enzyme immunosorbent assay and Western blot) • CSF for serum/CSF antibody index	• CSF for *Borrelia;* may be delay in CNS intrathecal synthesis • CSF PCR rarely positive (in contrast to synovial fluid) but may be useful in some cases
Brucella spp.	• CSF for IgG and IgM • CSF for culture • Serum for IgG and IgM	• Perform serology on both CSF and serum; culture increases sensitivity • PCR available in some research settings; unknown sensitivity
Leptospira spp.	• Serum IgM and IgG • Urine culture	• If serology negative on acute serum, important to repeat on convalescent serum
Listeria monocytogenes	• Routine bacterial culture	• May also be helpful to test CSF for *Listeria* antibody because detection of CSF antibody can indicate CNS infection
Mycobacterium tuberculosis	• CSF for acid-fast bacilli smear, culture, PCR, direct examination • Respiratory secretions for culture highly suggestive	• CSF PCR is insensitive; important to test multiple samples • Should be considered in patients with lymphocytic pleocytosis (but neutrophilic predominance can occur), with CSF protein >100 mg/dL or CSF glucose <50 mg/dL
Mycoplasma pneumoniae	• Nasopharyngeal swab or respiratory secretions for culture or PCR • Serum for IgM • Serum for IgG paired	• Pathogen of unknown neurologic potential • Perform PCR on respiratory samples, serology on acute/convalescent serum • CSF PCR rarely positive • Single IgG titer is not helpful • Single IgM test can have false-positive results
Treponema pallidum	• CSF for Venereal Disease Research	• Multiple tests as well as clinical findings are important for definitive diagnosis

	Laboratory (VDRL) test • CSF for fluorescent treponemal antibody (FTA) • CSF for PCR • Serum for VDRL and FTA	• CSF VDRL test is specific but CSF FTA is more sensitive • FTA does not distinguish between syphilis and other treponematoses such as pinta and yaws • Nontreponemal tests can have a prozone phenomenon resulting in false-negative FTA • Infection with *Borrelia burgdorferi* can cause false-positive FTA
RICKETTSIA		
Anaplasma phagocytophila	• Peripheral blood for morulae in neutrophils • Whole blood for PCR • Serum IgG/IgM (paired sera if possible)	• If serology negative on acute serum, important to repeat on convalescent serum
Coxiella burnetii	• Serum for acute and convalescent antibody	• Utility of PCR for *Coxiella burnetii* PCR for Q fever encephalitis unknown
Ehrlichia chaffeensis	• Morulae in peripheral blood monocytes • Whole blood for PCR • Serum for IgG/IgM (paired sera if possible	• If serology negative on acute serum, important to repeat on convalescent serum
Ehrlichia ewingii	• Morulae in peripheral blood granulocytes • Whole blood for PCR • Serum for IgG/IgM antibodies	• If serology negative on acute serum, important to repeat on convalescent serum
Rickettsia spp.	• Serum for indirect fluorescent antibody • Skin biopsy of rash for PCR or immunohistochemical staining	• If serology negative on acute serum, important to repeat on convalescent serum

A thorough history is crucial and should include an assessment of epidemiologic and clinical exposures as outlined in Table 44.1, with an emphasis on ill contacts, vector and animal exposures, outdoor activities, ingestions, and travel history. Any current or recent antecedent respiratory illness, gastrointestinal illness, or rash should be obtained because this may narrow the differential diagnosis or suggest a postinfectious syndrome such as ADEM.

Initial evaluation should include a complete blood count and tests of renal function and hepatic enzyme levels (Box 44.4). A baseline chest radiograph also should be obtained because focal infiltrates might be suggestive of certain pathogens (e.g., fungi or mycobacteria) and might prompt other diagnostic studies (e.g., bronchoscopy). An ophthalmologic examination also is suggested if there are supporting signs or symptoms because chorioretinitis may be identified in the newborn infant, or a migratory nematode in an older individual. Chorioretinitis also can be associated with WNE, bartonellosis, syphilis, histoplasmosis, tuberculosis, and noninfectious conditions such as sarcoidosis.[103]

Box 44.4

Initial Diagnostic Evaluation for Patients with Encephalitis

General Studies

CBC with differential

Renal function tests

Serum hepatic enzymes

Blood cultures

Chest radiograph

Ophthalmologic examination

Lumbar Puncture

Opening pressure

CSF WBC and RBC counts and differentials, protein, and glucose

Gram stain and culture for bacteria

PCR for herpes simplex virus and enterovirus

PCR for human parechovirus (<3 years of age)

Other tests as indicated based on specific host factors, exposures, clinical features

Serum for Antibody

Mycoplasma pneumoniae IgM/IgG

Epstein-Barr virus panel

Human immunodeficiency virus

Other tests as indicated based on specific host factors or exposures

Respiratory Secretions/Stool Specimen

PCR on respiratory tract specimen for enterovirus and *Mycoplasma pneumoniae*

PCR or culture on stool specimen for enterovirus

If respiratory symptoms: rapid tests, PCR panel, culture for influenza (during appropriate season) and other respiratory viruses

Neuroimaging

MRI (preferred; CT if not available)

Electroencephalogram

CBC, complete blood count; CSF, cerebrospinal fluid; CT, computed tomography; MRI, magnetic resonance imaging; PCR, polymerase chain reaction; RBC, red blood cell; WBC, white blood cell.

Neuroimaging is critical in evaluating encephalitis. Cranial computed tomography is helpful to identify abnormalities, such as ventriculomegaly, abscess, or tumor, and can help determine whether it is safe to perform a lumbar puncture (LP). However, magnetic resonance imaging is more sensitive for detecting changes of encephalitis.[104,105] Electroencephalography is an informative early test to assess for subclinical seizure activity and can help localize the region of affected brain.

An LP with measurement of the opening pressure and sampling for CSF analysis (cell count with differential analysis, glucose and protein concentrations), Gram stain, and culture should be performed unless there is a specific contraindication.[102,106] Results from the LP offer important clues as to whether the patient has an infectious or noninfectious etiology and whether an infectious cause is viral, bacterial, fungal, or parasitic. Fungal and mycobacterial testing should be performed selectively in suggestive cases. CSF viral culture is not recommended because its sensitivity is extremely low and may unnecessarily deplete the CSF sample.[107] PCR testing for viruses is more sensitive and rapid, including for herpesvirus, HPeV, and EV.[108,109] There are, however, important limitations of sensitivity and specificity for CSF PCR testing, as outlined in Table 44.4. The diagnostic test for HSE is CSF PCR testing for HSV DNA. If initial testing is negative and HSE is strongly suspected, the test should be repeated on a CSF specimen obtained a few days after the first LP.[1] For HSE and VZV encephalitis, intrathecal antibody assays can be performed to supplement nucleic acid testing.[110] For many of the arboviruses, antibody testing of serum or CSF is preferred to PCR testing because peak viremia generally occurs before symptom onset.

In patients with respiratory symptoms, respiratory specimens should be tested for common viral pathogens early in hospitalization to optimize detection. Molecular and antigen detection testing is more sensitive than culture. If diarrhea is present, a stool specimen should be obtained for viral pathogens. In a young child, a stool viral culture or enterovirus PCR should be performed to optimize enterovirus detection, regardless of presence of diarrhea, and in the appropriate setting, rotavirus antigen testing performed.[111]

An extra red-topped serum tube should be collected in the acute phase of illness and held for later serologic studies. A convalescent serum should be collected 10 to 21 days later. Although immediate management is not altered, documentation of seroconversion or a fourfold rise in titer can determine the diagnosis (see Box 44.4).

Brain biopsy is rarely performed but has value in selected cases because of limitations in both molecular and serologic methods. The utility of targeted brain biopsy was illustrated in a series of 16 patients with unknown CNS illnesses, detecting bacterial abscess (6), toxoplasmosis (3), HSV (1), *Aspergillus* infection (2), and *M. tuberculosis* infection (2) that were not detected by other methods.[112] Biopsy also is helpful for diagnosis of noninfectious entities such as small vessel vasculitis and intravascular lymphoma.[113] In the event of the death of a patient with undiagnosed encephalitis, an autopsy should be sought to determine the cause of death.

Laboratory Findings

Routine laboratory studies (see Box 44.4) infrequently help to identify specific etiologies but can suggest particular etiologies. For instance, finding leukopenia, thrombocytopenia, and elevated serum transaminase levels during summer months would be suggestive of CNS *Ehrlichia* disease.[114] Additionally, test results guide appropriate dosing regimens for antimicrobial therapy.

Most patients with viral encephalitis have CSF mononuclear cell pleocytosis, with cell counts ranging from 10 to 200 mg/dL.[3] However, early in the course, pleocytosis can be absent or show neutrophil predominance. Repeat LP in 1 to 2 days may be useful.[115] The CSF protein level generally is elevated (usually <100 mg/dL), whereas the glucose level is normal or minimally low, with a few important exceptions (LCM and mumps).

Neutrophilic pleocytosis (particularly with CSF WBC count >1000 cells/mm^3, protein >200 mg/dL, or CSF glucose less than two thirds of blood concentration) is suggestive of a bacterial entity. In fungal infections moderate lymphocytic pleocytosis usually is found. *Naegleria* infection generally elicits extreme CSF neutrophilic pleocytosis. Eosinophils in the CSF suggest infection due to a parasite (e.g., *B. procyonis, Angiostrongylus* spp., or *G. spinigerum*), *M. tuberculosis,* or *Coccidioides* spp. As noted in Table 44.4, there are important considerations if eosinophils are detected in spinal fluid.

Management

Management should focus on treatable and common causes of encephalitis.[102] Empiric treatment for bacterial meningitis (vancomycin plus a third-generation cephalosporin) should be started because the clinical presentation can overlap with encephalitis. Therapy with ampicillin is considered additionally when rhomboencephalitis is present or there is significant cellular immunocompromise (e.g., chronic corticosteroid use). HSE is one of the few treatable causes of viral encephalitis; therapy with high-dose parenteral acyclovir should be started and continued until HSV-1 has been reasonably excluded as a diagnosis, which can require serial CSF samples. Antiviral therapy considerations generally are restricted to treatment of herpesviruses (HSV-1 and

VZV) and the unusual instance of HIV infection.[102] Therapy for tuberculous or fungal meningitis should be initiated empirically when clinical and laboratory testing is compatible. If rickettsial or *Ehrlichia* infections are suspected, doxycycline should be initiated empirically. For influenza-associated encephalitis, oseltamivir, although not proved to be efficacious, is given and may be beneficial.[116] Corticosteroids and immune globulin intravenous also may be helpful in some influenza-associated encephalitis cases because a mechanism of hyperintense cytokine response is suggested.[116] There is no evidence that treatment of CNS *Mycoplasma* infection alters outcome.

In addition to directed therapy, aggressive supportive care is critical, and minimizing secondary brain injury is a high priority.[117] Cerebral edema should be considered in patients who are not improving with empiric antimicrobial and supportive therapy. Physicians frequently neglect to measure CSF opening pressure, which may be a helpful clue to impending complications. Repeat neuroimaging to monitor for cerebral edema is particularly important in comatose patients. Typical indicators of elevated intracranial pressure, such as poorly reactive dilated pupils, decorticate or decerebrate posture, or Cushing triad (systolic hypertension, bradycardia, and shallow respirations) are late findings. Subclinical seizures are common; continuous electroencephalographic monitoring is considered in patients with persistent alteration in mentation.[118] Patients should be monitored for the syndrome of inappropriate secretion of antidiuretic hormone. If hyponatremia is present, it is important to correct sodium levels slowly to avoid the complication of extrapontine osmotic myelinolysis.[119]

Conditions that mimic infectious encephalitis should be considered, and metabolic and toxic disorders causing encephalopathy and seizures should be excluded. Anti-NMDAR encephalitis is of particular importance given its high incidence and therapeutic considerations.[62,120] As outlined in Chapter 45, in patients suspected to have postinfectious encephalitis or ADEM, often with a characteristic magnetic resonance image showing prominent white matter inflammation, corticosteroid or other immunotherapy often is recommended.

Complications and Prognosis

In a large cohort of pediatric patients with encephalitis due to a variety of causes, one third of patients had incomplete recovery, and 6.8% of patients died.[121] Prognosis is highly dependent on the specific infectious cause. Rabies and *N. fowleri*, for instance, have an almost 100% fatality rate. Even with effective antiviral therapy, >35% of patients with HSE suffer severe sequelae or death.[122,123] Relapse of HSV-1 encephalitis, both early (within weeks of disease onset) and late (within months to years), is described in up to 26% of children.[124] In addition, the anti-NMDAR autoimmune form of encephalitis can be triggered by HSE, in which case immunosuppressive therapy is indicated.[125]

WNND has a much better prognosis in children than in adults. From 2003 to 2012, of 505 pediatric WNND disease cases, most (88%) were hospitalized, but the case-fatality rate was <1%[28]; this contrasts with WNV case-fatality rates of 9% overall (all ages) and 17% for individuals ≥60 years.[126] LACV and EEE cause more severe neurologic disease in children than WNV.[127] In a study of 127 children with LACV, 12% had neurologic deficits at discharge.[127] EEE also is known to have a higher mortality rate (almost 30%) and potentially severe neurologic complications.

Other viral etiologies are less well studied, with information limited to case reports and small series. Persistent neurologic deficits after EBV encephalitis are reported to be rare.[123] ANE associated with influenza has a high mortality rate, with most fatalities reported in Japan and Taiwan.[128,129] In the US, ANE cases are less common and appear to have better outcome.[130]

Bacterial infections causing meningoencephalitis are associated with significant morbidity despite the availability of effective antibiotic therapies. In a French study, *L. monocytogenes* and *M. tuberculosis* meningoencephalitis accounted for 46% of fatalities due to encephalitis.[131] *L. monocytogenes* infections are less common in the US.[132] Tuberculous meningoencephalitis was associated with a 30% mortality, with 40% of survivors suffering moderate or severe disabilities.[133] On the other hand, encephalopathy due to *Bartonella* spp. is associated with an excellent outcome, with >90% of patients recovering completely without sequelae.[134]

Although studies are limited, one study reported significant sequelae in up to 53% of survivors hospitalized for encephalitis ultimately of unknown cause.[135]

Progress in Treatment and Prevention

Progress is being made toward treatment of some infections once considered to be universally fatal. In 2004, an unvaccinated adolescent survived rabies encephalitis after a novel therapy was used.[136] Good outcomes have been achieved with various combination drug regimens for *B. mandrillaris* and *B. procyonis*.[137–139] In 2015, a third well-documented survivor of *N. fowleri* was reported after miltefosine therapy.[140] Pleconaril-like compounds are being tested against some enteroviruses.[141]

Routine immunizations decrease dramatically encephalitis related to diseases such as measles, mumps, rubella, varicella, and influenza, and postexposure rabies immune globulin plus vaccine prevents rabies. For the immunocompromised host, passive postexposure prophylaxis for varicella and measles also is available. Avoidance of exposure to arthropod vectors is an effective means of preventing arboviral and tickborne encephalitis. EV-71 vaccine candidates are in clinical trials.[142]

Parainfectious and Postinfectious Neurologic Syndromes

Jonathan B. Strober, Carol A. Glaser

Inflammation of the central or peripheral nervous system can produce a myriad of symptoms depending on site. The inflammation often arises during, or in response to, an infection. However, the same syndrome can be seen when there have been no signs of a preceding illness, and occasionally the syndrome can develop after vaccination. The presentation can be localized to one structure, such as in optic neuritis (ON), or affect multiple structures, such as in acute disseminated (or demyelinating) encephalomyelitis (ADEM). Inflammation typically causes temporary demyelination, although it can cause injury to the underlying parenchyma or axons, leading to more permanent injury. The focus of this chapter is the more common syndromes seen in the pediatric population, their various etiologies, diagnostic evaluation, and management (Tables 45.1 and 45.2).

TABLE 45.1

Etiologies of Parainfectious and Postinfectious Syndromes of the

Central Nervous System

ACUTE DISSEMINATED ENCEPHALOMYELITIS	**Viruses**	**Bacteria**	**Noninfectious Associations**
	Enteroviruses	*Bartonella henselae*	Adrenoleukodystrophy
	Epstein-Barr virus	*Borrelia burgdorferi*	Behçet syndrome
	Herpes simplex virus 1 and 2	*Streptococcus pyogenes*	CNS lymphoma
	Influenza A and B	*Leptospira* sp.	Langerhans cell histiocytosis
	Measles virus	*Mycoplasma pneumoniae*	Metachromatic leukodystrophy
	Mumps virus	**Parasites**	Mitochondrial disorders
	Parainfluenza viruses	*Plasmodium falciparum*	Multiple sclerosis
	Rubella virus		Primary CNS vasculitis
	Varicella-zoster virus		Systemic lupus erythematosus
	Variola virus		Sjögren syndrome
			Sarcoidosis
			Vaccines
ACUTE FLACCID MYELITIS	**Viruses**		
	Poliovirus		
	Enteroviruses		
	West Nile virus		
	Japanese encephalitis virus		
TRANSVERSE MYELITIS	**Viruses**	**Bacteria**	**Noninfectious Associations**
	Enterovirus	*Bartonella henselae*	Antiphospholipid antibody syndrome
	Epstein-Barr virus	*Borrelia burgdorferi*	Ischemic myopathy
	Herpes simplex virus 1 and 2	*Streptococcus pyogenes*	Neuromyelitis optica (Devic disease)
	Influenza A and B	*Leptospira* sp.	Spinal cord tumor
	Measles virus	*Mycoplasma pneumoniae*	Sjögren syndrome
	Mumps virus	**Parasites**	Systemic lupus erythematosus
	Parainfluenza viruses	*Plasmodium falciparum*	
	Rubella virus	*Schistosoma* spp.	
	Varicella-zoster virus	*Toxocara canis*	
	Variola virus		
CEREBELLITIS	**Viruses**	**Bacteria**	**Noninfectious Associations**
	Adenovirus	*Borrelia* spp.	Antineuronal antibodies (e.g., anti-Hu)
	Cytomegalovirus	*Coxiella burnetii*	Methadone ingestion

	Enteroviruses	*Rickettsia* spp.	Systemic lupus erythematosus
	Herpes simplex virus 1 and 2	*Salmonella typhi*	Tick paralysis
	Human herpes virus 6		Vaccines
	Human immunodeficiency virus		
	Influenza virus		
	Mumps virus		
	Rotavirus		
	Varicella-zoster virus		
	West Nile virus		

CNS, central nervous system.

TABLE 45.2

Etiologies of Parainfectious and Postinfectious Syndromes of the Peripheral Nervous System

GUILLAIN-BARRÉ SYNDROME	**Viruses**	**Bacteria**	**Noninfectious Associations**
	Cytomegalovirus	*Campylobacter* spp.	Chronic progressive external ophthalmoplegia
	Epstein-Barr virus	**Mimicking**	Heavy metal poisoning
	Herpes simplex virus 1 and 2	Infant botulism	Myasthenia gravis
	Varicella-zoster virus	Poliovirus	Tick paralysis
		West Nile virus	Vaccines
FACIAL NERVE PALSY (BELL)	**Viruses**	**Bacteria**	**Noninfectious**
	Herpes simplex virus 1	*Borrelia* spp.	Aneurysm of vertebral, basilar or carotid arteries
	Epstein-Barr virus	*Mycobacterium tuberculosis*	Cholesteatoma of the middle ear
	Human herpesvirus 6	*Mycobacterium leprae*	Drugs (e.g., linezolid)
	Human immunodeficiency virus Parvovirus B19 Varicella-zoster virus	**Mimicking**Acute otitis media Intraparotid lymphadenitis Necrotizing otitis externa Osteomyelitis of the skull base Parotid gland abscess	Kawasaki disease Leukemic meningitis
			Parotid tumors
			Sarcoidosis
			Fracture of base of the skull
			Fracture of the temporal bone
			Trauma
OPTIC NEURITIS	**Viruses**	**Bacteria**	**Noninfectious Associations**
	Chikungunya virus	*Bartonella henselae*	ADEM
	Varicella-zoster virus	**Parasites**	Autoimmune (IBD, SLE)
	West Nile virus	*Angiostrongylus cantonensis*	Copper deficiency

		Baylisascaris procyonis	Diabetes mellitus
		Toxocara canis/cati	Drugs (e.g., ethambutol)
		Treponema pallidum	Neuromyelitis optica (Devic disease)
			Multiple sclerosis
			Vasculitis
OCULOMOTOR NEUROPATHY	**Viruses**	**Infectious**	**Noninfectious Associations**
	Varicella-zoster virus	Brain abscess	Aneurysm
		Meningitis	Congenital palsy
			Diabetes mellitus
			Myasthenia gravis
			Sarcoidosis
			CNS tumor
			Trauma

ADEM, acute disseminated encephalomyelitis; CNS, central nervous system; IBD, Inflammatory bowel disease; SLE, systemic lupus erythematosus.

Cranial Nerve Palsies

Facial Nerve Palsy (Bell Palsy)

The most common parainfectious neurologic syndrome is inflammation of the peripheral facial nerve (cranial nerve [CN] VII). When no etiology is identified, the condition often is referred to as *Bell palsy*. One study reported an incidence of 4.2 per 100,000 children <10 years of age, increasing to 15.3 per 100,000 in children aged 10 to 20 years.[1] There are no seasonal or sex differences. Palsy typically is unilateral, is acute in onset, and often develops after a preceding illness. Facial nerve palsy also can occur in conjunction with peripheral nervous system involvement.

There are two proposed pathologic mechanisms, both leading to edema and entrapment of the nerve in the facial canal. The most likely explanation is direct inflammation of the nerve. Magnetic resonance imaging (MRI) can show gadolinium enhancement of the nerve,[2] and pathologic studies describe lymphocytic infiltration and associated demyelination or axonal degeneration.[3] Another possibility is that increased capillary permeability, as occurs in diabetes, leads to edema and compression of the nerve's microcirculation. This mechanism is supported by the finding that diabetic people are 2.5 times more likely to develop Bell palsy than people without diabetes.[4]

Herpes simplex virus (HSV) has been the most frequent virus associated with Bell palsy,[5] although other viruses, including Epstein-Barr virus (EBV) and hepatitis B virus, have been implicated. Ramsay Hunt syndrome, a rare complication of latent varicella-zoster virus (VZV) infection, is defined as an acute peripheral facial neuropathy associated with an erythematous vesicular rash of the skin of the ear canal, auricle (also termed *herpes zoster oticus*), or mucous membrane of the oropharynx. *Borrelia burgdorferi* infection also can cause facial palsy, which can develop without a history of tick bite or erythema migrans.[6] In one study in a Lyme disease endemic area, 34% of people ≤20 years of age who were evaluated in the emergency department because of facial palsy were found to have Lyme disease.[7] Facial palsy due to Lyme disease often is bilateral, associated with accompanied headache and fever, and typically occurs from June through October.

Treatment is aimed at the underlying etiology, but good eye care is important to protect the cornea. Bacterial causes should be treated with appropriate antibiotics. Cases due to Lyme disease should be treated with doxycycline or amoxicillin for 14 to 21 days to prevent late disease; treatment has no effect on resolution of the facial nerve palsy.[8] Most palsies resolve without treatment. A meta-analysis of adults and children with Bell palsy demonstrated a 17% improvement with corticosteroid treatment compared with no treatment.[9] There is controversy regarding whether acyclovir should be used to treat acute Bell palsy because many cases are associated with HSV infection. The addition of an antiviral agent to corticosteroid therapy, even when used in the first 72 hours of onset of illness, does not appear to improve outcome.[10] The extent of facial nerve recovery does not necessarily relate to the severity of the initial nerve involvement.[11]

Optic Neuritis

The second most common cranial nerve to be affected by parainfectious demyelination is the optic nerve. ON has been reported to have an incidence of 0.2 per 100,000 in Canadian children,[12] similar to that of ADEM and transverse myelitis (TM). ON typically manifests with reduced vision (e.g., blurred or “foggy” vision) and pain with eye movement. ON can be accompanied by other neurologic signs or symptoms, as is seen in ADEM, or can be the heralding manifestation of multiple sclerosis (MS) or neuromyelitis optica (NMO; Devic disease). Therefore brain MRI is recommended for patients with isolated ON. Up to 85% of cases are preceded by an infection or vaccination, and most patients regain at least 20/40 vision.[13]

Females are more commonly affected than males[12,14,15]; however, female sex does not necessarily increase the risk for subsequently developing MS. ON often is unilateral but can be bilateral.[15] On funduscopic examination, the head of the optic nerve may be swollen but can appear normal even to an experienced ophthalmologist. The presence of white matter lesions on MRI disseminated in space and time (more than one episode) is the strongest predictor for developing MS[14,15]; a normal MRI at first-episode ON does not preclude the development of MS.[16] The presence of NMO antibodies is highly specific for the diagnosis of Devic disease; their sensitivity is approximately 80%.[17] Brain MRI often is normal in this condition.

Bartonellosis is one of the most common infectious causes of isolated ON as well as when accompanied by lymphadenopathy and fever. Arboviruses, including West Nile virus[18] and chikungunya,[19,20] also have been associated with ON. Animal roundworms, e.g., *Toxocara canis* and *Baylisascaris procyonis,* are rare causes of ON. When these nematodes invade the eye, a neuroretinitis also can occur and the worm itself is sometimes visualized in the retina. *Angiostrongylus cantonensis* (a cause of eosinophilic meningitis) is found in Southeast Asia, the South Pacific, Australia, the Caribbean, and some areas of the United States (Louisiana and with increasing frequency in Hawaii) and also can cause ON.

The typical treatment for ON is a 3-day course of high-dose corticosteroid administered intravenously followed by a short oral taper, regardless of underlying cause. Additional treatment with specific antimicrobial therapy may be needed depending on the cause. In 1992, the Optic Neuritis Treatment Group found that treatment with intravenous (IV) corticosteroid hastened recovery over placebo, but did not change long-term outcome.[21] Treatment with oral corticosteroids did not seem to affect outcome, although patients receiving oral therapy relapsed more frequently than those receiving IV therapy. Prognosis is good, with visual acuity at or near baseline in at least 70% of patients.

Ocular Motor Nerve Palsies

Isolated neuropathies affecting one of the three nerves that move the eye, the oculomotor nerve (CN III), trochlear nerve (CN IV), and abducens nerve (CN VI) have been reported to occur as a postinfectious entity.[22] These are rare conditions that often do not require treatment. However, more common causes of these neuropathies, such as trauma, increased intracranial pressure, tumor, and vascular causes, should be excluded. Ocular motor palsies also are associated with the Miller-Fisher variant of Guillain-Barré syndrome (GBS).

Cerebellitis

Apart from affecting individual nerves in the central nervous system (CNS), the cerebellum can become inflamed because of an infectious or postinfectious process, commonly known as *cerebellitis* or *acute cerebellar ataxia*. Acute-onset ataxia is typical and often is self-limited with complete recovery. It is estimated to occur in approximately 1 per 100,000 to 500,000 children,[23] although it is difficult to determine an accurate incidence because many children with mild disease may not come to medical attention or may be evaluated only by their primary care physician.

Cerebellitis often presents concurrently with a viral illness, with VZV having the best recognized association. Cerebellitis also has been reported in association with EBV, *Mycoplasma pneumoniae*, *Listeria*, mumps, and enterovirus, as well as vaccinations.[23,24] Pathologic studies have shown inflammation, primarily composed of T lymphocytes, of the leptomeninges and molecular layer of the cerebellum. Imaging typically demonstrates enhancement of the cerebellum, localized mostly to the leptomeninges (Fig. 45.1).[24] Cerebrospinal fluid (CSF) analysis can be normal or show mild mononuclear pleocytosis and elevated protein concentration.

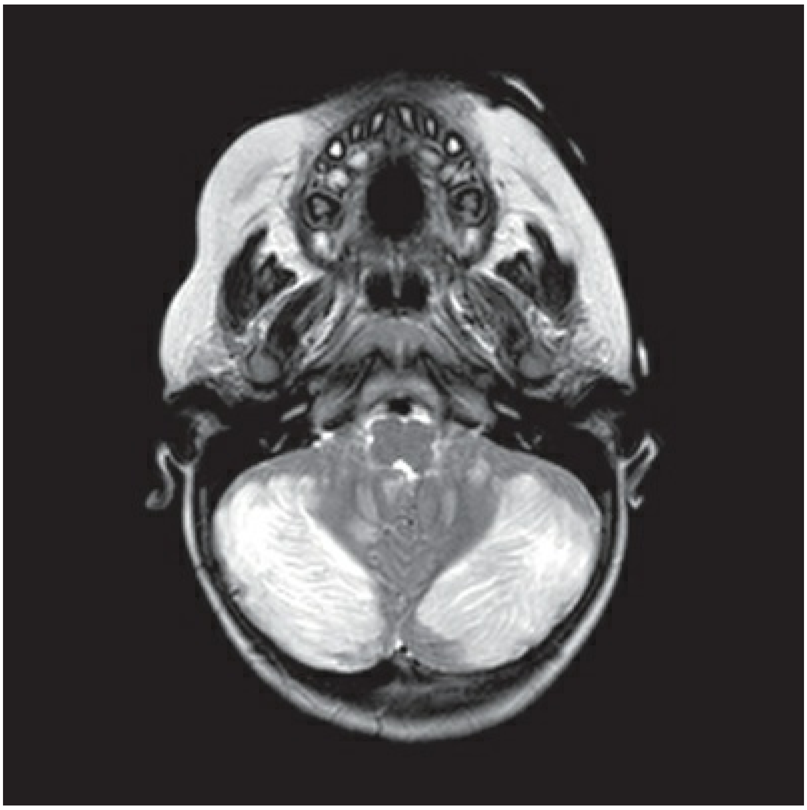

FIGURE 45.1 Brain magnetic resonance image from a patient with cerebellitis and diffusely increased fluid-attenuated inversion recovery T2 signal. (Courtesy of Brian Lee, MD, Children's Hospital & Research Center, Oakland, CA.)

Management is supportive; however, owing to its location, cerebellar swelling can lead to acute and severe hydrocephalus, eventually causing herniation and brainstem compression. In severe cases, corticosteroid therapy is indicated to help minimize swelling and prevent complications.[25]

Acute Disseminated Encephalomyelitis

ADEM usually is a monophasic polysymptomatic disorder that can affect any part of the brain and spinal cord. ADEM has an estimated incidence of 0.4 to 0.8 per 100,000, accounting for about 10% to 15% of cases of encephalitis in the US.[12,26,27] Neurologic symptoms often develop 2 to 4 weeks after an infection or vaccination and typically progress quickly, often over hours to days.[27] Up to 75% of cases of ADEM have an identifiable trigger. Historically, vaccine-preventable diseases such as measles and mumps were common precedents of ADEM. Measles virus can cause direct viral encephalitis and also is considered one of the most important triggers of ADEM. In countries where vaccines are widely used to prevent measles, mumps, rubella, and varicella infections, upper respiratory infections are the most common illnesses preceding ADEM. Vaccines also can trigger ADEM. The incidence of measles vaccination−associated ADEM is reported to be 0.1 per 100,000, compared with 0.2 to 0.3 per 100,000 after wild-type measles infection.[28] ADEM also has been reported temporally associated with human papillomavirus vaccination.[29]

Clinical manifestations of ADEM include altered mental status in 50% to 75% of cases and seizures in 10% to 35% of cases.[27] The presenting symptoms vary according to the regions of the CNS that are affected, which differ substantially from patient to patient. Motor weakness (e.g., acute hemiparesis), ataxia, decreased verbal output or mutism, cranial neuropathies, and urinary disorders are common.[30]

Less than one third of patients with ADEM have a recurrent or multiphasic course, which can be difficult to distinguish from MS in some instances.[27] Recurrent ADEM is defined as a new event with recurrence of initial symptoms ≥3 months after the first event and ≥1 month after discontinuing corticosteroid therapy; MRI does not show new lesions in ADEM, although original lesions may have enlarged.[31] Involvement of the deep grey structures such as basal ganglia and thalamus can occur in ADEM, whereas these structures rarely are involved in MS.

Many disorders can have MRI appearance similar to ADEM. These include systemic immunologic and inflammatory disorders such as systemic lupus erythematosus, sarcoidosis, Behçet syndrome, and Langerhans cell histiocytosis, which often have multisystem involvement. Meningitis, meningoencephalitis, and brain abscesses or tumors usually are easily distinguishable from ADEM. However, some infectious agents, such as *Balamuthia mandrillaris* and *Baylisascaris procyonis,* can have MRI changes that can be confused with ADEM due to T2 signal changes in the white matter. Metabolic disorders, such as adrenoleukodystrophy and metachromatic leukodystrophy, tend to manifest more insidiously, whereas mitochondrial disorders can cause acute T2 signal lesions on neuroimaging but tend to have more of a relapsing and remitting course.

The diagnosis of ADEM is based primarily on the clinical course and MRI findings (Fig. 45.2). Lumbar puncture should be performed to exclude infectious etiologies. The most common CSF abnormalities are a mild pleocytosis (usually with lymphocytic predominance) and elevation in protein concentration. Evaluation for the presence of oligoclonal bands should be performed when MS is considered. However, the presence of oliogoclonal bands does not confirm a diagnosis of MS because they can be found in up to almost 30% of patients with ADEM.[32]

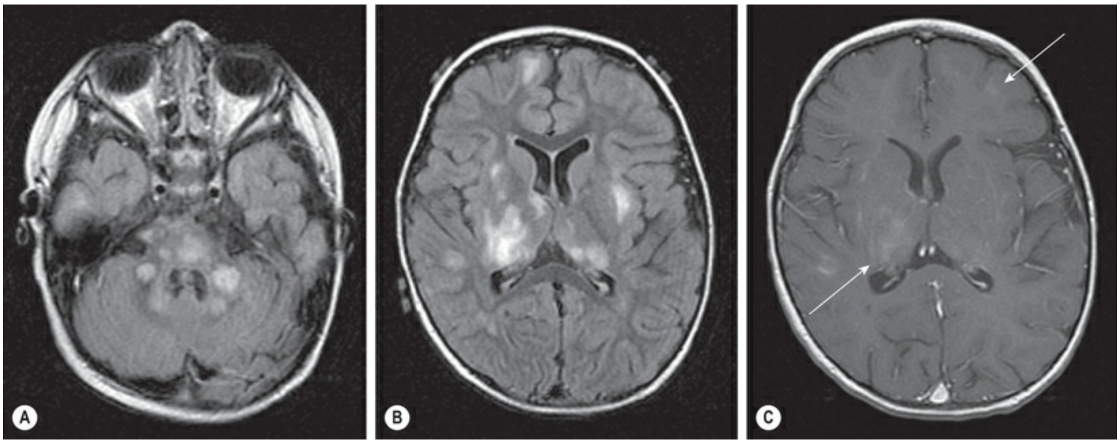

FIGURE 45.2 Brain magnetic resonance images from patient with acute disseminated encephalomyelitis showing multiple hyperintense lesions in the cerebellum and brainstem (A) as well as deep and superficial white matter and deep grey matter (B) with subtle patchy enhancement (*arrows* in C).

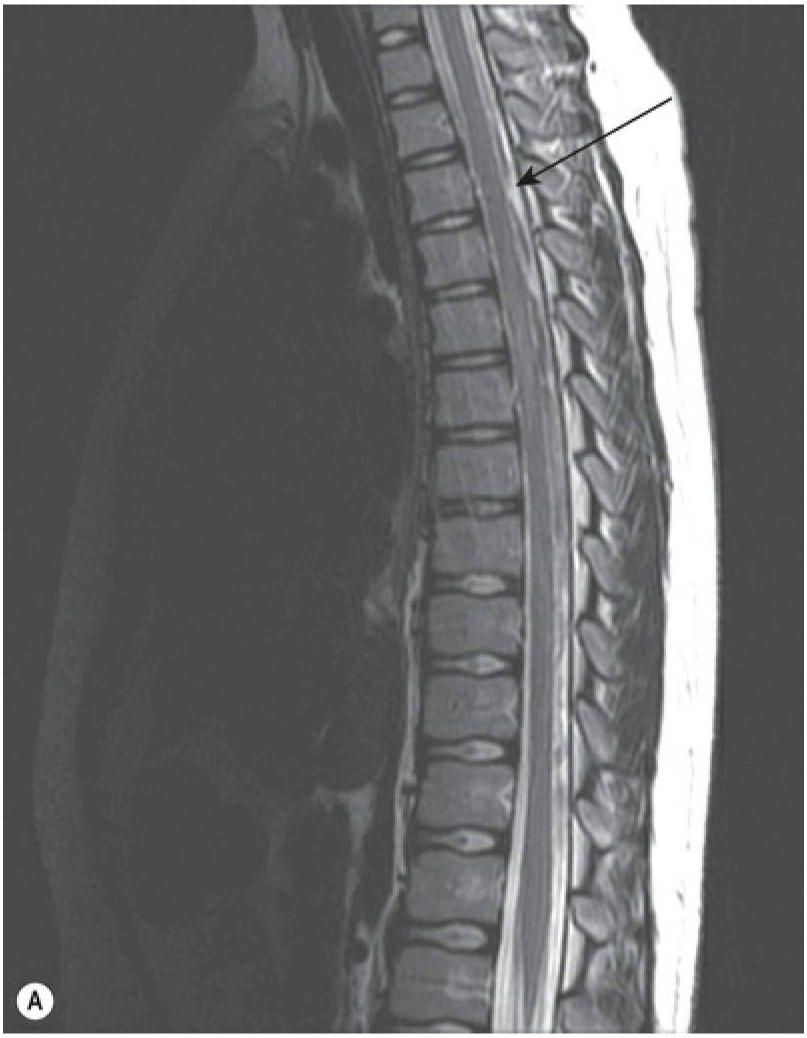
High-dose corticosteroid therapy is first-line therapy for ADEM.[33] Immune globulin intravenous (IGIV) or plasmapheresis often is used if there is no response to corticosteroid. Immunomodulating agents, such as cyclophosphamide, sometimes are used in refractory cases. Recovery often is complete, although residual deficits can occur in up to 30% of patients.

Transverse Myelitis

TM can occur in association with ON, neuromyelitis optica, or cerebral lesions (ADEM) or in isolation. Approximately 1400 new cases of isolated TM occur each year in the US, 20% in children <18 years of age.[34] In a Canadian cohort, the incidence was reported as 0.2 per 100,000, which is similar to the incidence of ADEM and ON.[12] Incidence is approximately equal in males and females. TM has been reported in infants as young as 6 months of age. Approximately 50% to 75% of cases have a history of a preceding illness, often a presumed respiratory tract infection, or vaccination.[34,35]

Diagnosis of TM is based on evidence of spinal cord inflammation, such as CSF pleocytosis, increased CSF immunoglobulin G index, or gadolinium enhancement on MRI (Fig. 45.3), and lack of an alternative etiology. Presenting symptoms depend on the affected area but often begin with back pain with progression to loss of bowel and bladder function as a result of autonomic dysfunction and lower extremity weakness and sensory loss. MRI is abnormal in 80% to 95% of patients, typically showing involvement of >3 vertebral bodies in length.[35] CSF is abnormal in up to 70% of patients, often showing elevated protein and less often an increased white blood cell count.



A

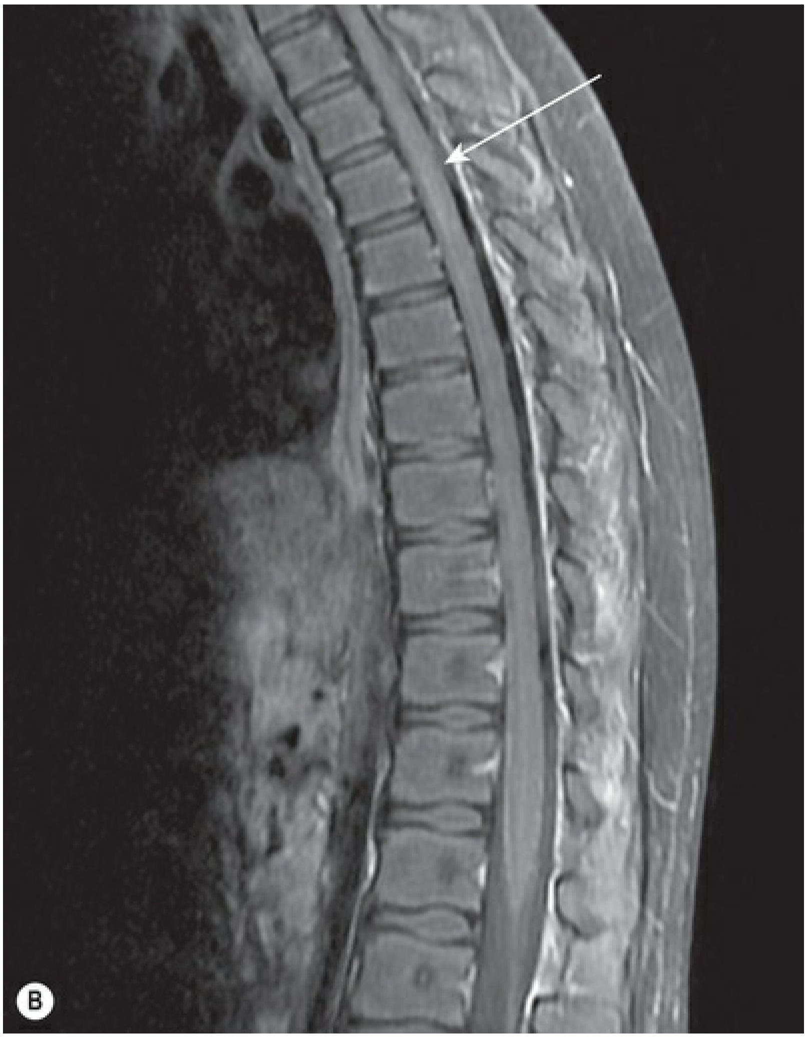


FIGURE 45.3 Thoracic spine magnetic resonance images from patient with transverse myelitis showing increased T2 signal (*arrow* in A) and patchy gadolinium enhancement (*arrow* in B).

A number of different infections, similar to those associated with ADEM, have been implicated as causes of TM (see Table 45.1). Enteroviruses are one of the most frequently implicated causes.[36]

The mainstay of treatment of TM is corticosteroids. Plasma exchange or IGIV also sometimes is used. Recovery often is not complete, and treatment has not been associated with improved outcome. The most common neurologic deficit is impaired bladder control,[34] but >25% of children with TM require ongoing assistance with self-care activities. Younger age, longer time to diagnosis, and larger extent of lesions are associated with poorer prognosis.

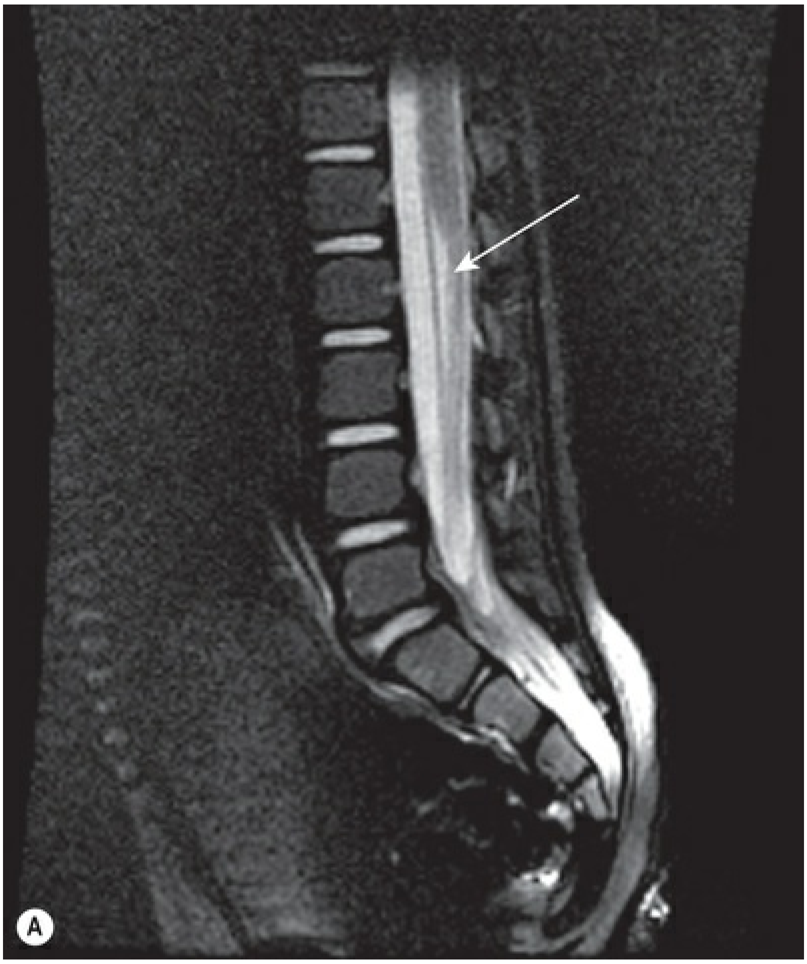
Acute Inflammatory Demyelinating

Polyradiculoneuropathy (Guillain–Barré Syndrome)

Acute inflammatory demyelinating polyradiculoneuropathy, better known as GBS, is an acute to subacute disorder often associated with ascending paralysis, but there are several variants. In the postpolio era, GBS is the most common cause of acute motor paralysis in children, with an estimated incidence of 0.5 to 1.5 per 100,000 people <18 years of age,[37] and with a slight male predominance.

In the classical form of GBS, extremity weakness is accompanied by areflexia and occurs in an ascending pattern. Sensory and autonomic symptoms, including urinary retention, cardiac arrhythmias, and autonomic instability, are common. Radicular back pain is a frequent initial complaint. Symptoms often are preceded by a gastrointestinal or upper respiratory tract illness. *Campylobacter jejuni* infection[38] and influenza vaccine are the most commonly identified specific precipitants of GBS.[39] In the US, 95% of cases are the classical demyelinating sensorimotor neuropathy form.[40] Other forms include axonal forms (both acute motor and sensorimotor), which account for up to 30% of cases in China and Latin America, and the Miller-Fisher variant, characterized by ataxia and ophthalmoplegia. Cranial nerve involvement also can occur in the classical form.

Electromyography and nerve conduction studies (EMG/NCS) can be helpful in diagnosing GBS, with findings consistent in almost 70% of cases in one pediatric series.[40] However, electrophysiology can be normal for up to a week into the illness, with the initial abnormality often being prolongation of the F wave, a measure of proximal nerve conduction. EMG/NCS can be helpful in excluding other conditions, such as infant botulism and myasthenia gravis, if ophthalmoparesis is present, as well as other neuropathies, such as heavy metal poisoning. The most typical CSF finding is albuminocytologic dissociation, that is, elevated protein without pleocytosis; however, CSF with white blood cell counts $>50/\text{mm}^3$ has been observed.[40] MRI can be helpful diagnostically, occasionally showing hyperintensity of the anterior nerve roots (Fig. 45.4).



A

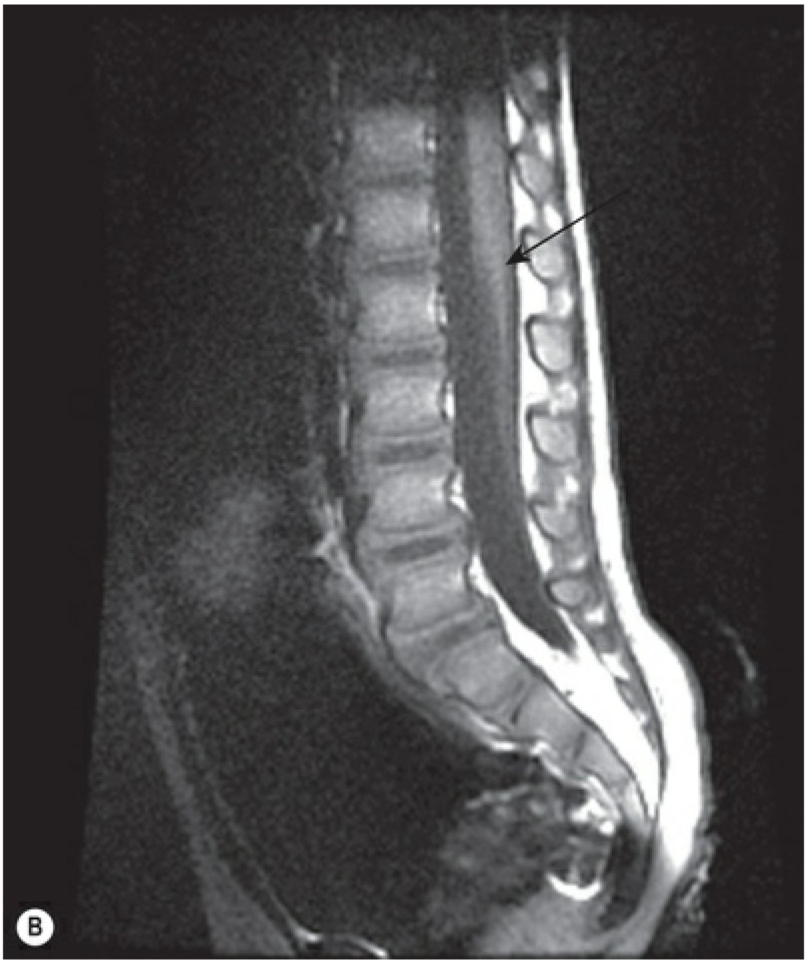


FIGURE 45.4 Magnetic resonance images of lumbar spine from patient with Guillain-Barré syndrome showing increased T2 signal in the cauda equina (*arrow* in A) with smooth enhancement (*arrow* in B).

Clinically, GBS symptoms plateau eventually, and then recovery begins. Respiratory support may be necessary during the nadir of the illness. Expert guidance, published in 2003, recommends plasma exchange for nonambulatory patients within 4 weeks of symptoms.[41] Plasma exchange also should be considered in ambulant patients who present within 2 weeks from symptom onset. IGIV is considered equivalent to plasma exchange in patients who require aid to walk and is associated with less frequent complications. Therefore IGIV is used more often as first-line therapy. Unlike a number of the other parainfectious conditions, corticosteroids are not recommended for treatment of GBS.

Overall, children with GBS have a good prognosis. Up to 95% of children are symptom free or only minimally affected 2 years after onset.[42,43] Mortality in GBS is low, occurring in <10% of patients,[42] mostly from respiratory failure and often in association with cardiac arrhythmia or autonomic dysfunction.

Acute Flaccid Myelitis

Acute flaccid myelitis (AFM) is a syndrome defined by rapid onset of weakness in one or more limbs, shortly after an upper respiratory tract infection or gastrointestinal illness, with absent deep tendon reflexes and normal sensory examination, mimicking that seen decades ago before the eradication of poliovirus in all but 3 countries.[44] AFM has been reported in association with other viruses over the years, most significantly West Nile virus and enterovirus 71.[45,46] During an outbreak in the US of enterovirus D68 during 2014, 107 children in 34 states developed this condition,[47] raising the potential connection between the virus and the condition. Enterovirus D68 was detected in respiratory samples in two thirds of patients from a cluster of patients who presented during the outbreak in Colorado and California and grouped into clade B1, which emerged in 2010.[48]

MRI often shows lesions predominantly in the anterior horn, which can be longitudinally extensive (Fig. 45.5). Acute enhanced T2 signal lesions involving the brainstem also were seen frequently in the recent enterovirus D68–associated outbreak.[49] Nerve conduction studies often are normal early on, and electromyography shows decreased recruitment of motor units with eventual development of fibrillation potentials (personal experience). CSF characteristically shows a pleocytosis with normal to mildly elevated protein and normal glucose concentrations.[47,48]

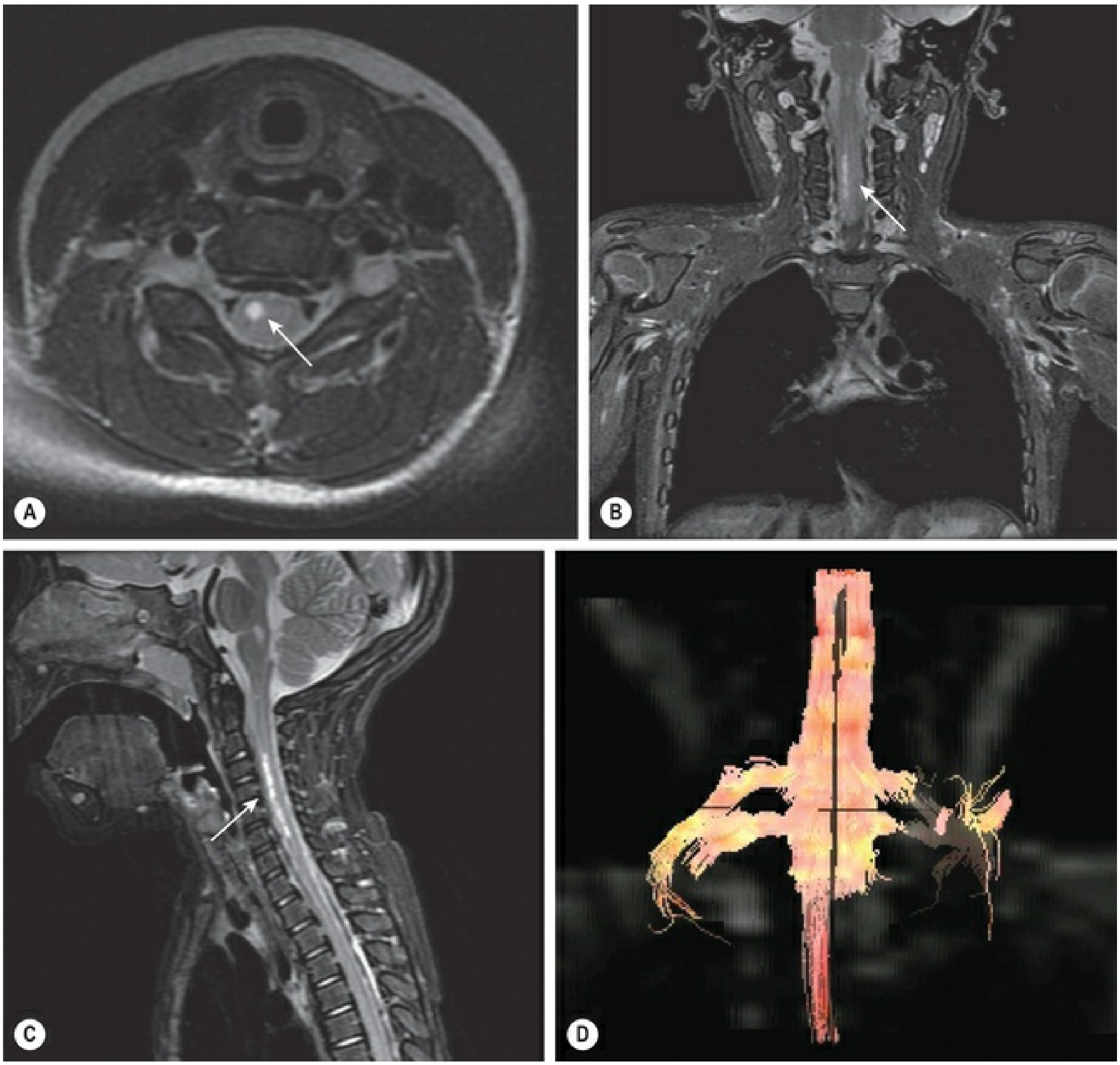

FIGURE 45.5 Magnetic resonance images of the brain and spinal cord from a patient with acute flaccid myelitis showing increased T2 signal in the anterior horn on axial (*arrow* in A), coronal (*arrow* in B) and sagittal (*dashed arrow* in C) images and in the brainstem (*solid arrow* in C). Diffusion tensor imaging shows absence of C5 and C6 nerve roots after exiting the spinal cord (D).

Treatments such as IGIV, corticosteroids, and plasma exchange have not been helpful for most patients.[47] Most patients have long-term persistent motor deficient (personal experience) requiring ongoing physical and occupational therapy. Nerve transfer and grafting have been performed in many children, but long-term follow up is not yet available to assess value.

Focal Suppurative Infections of the Nervous System

Christopher J. Harrison

Diverse microorganisms cause focal suppurative nervous system infections; however, most are due to a few, mostly gram-positive species. The causative pathogen and anatomic site are usually linked to the original portal of entry.

Risk factors include cyanotic congenital heart disease (CCHD), hematogenous dissemination from distant persistently infected sites, regional penetrating trauma or instrumentation, and contiguous sinus, middle-ear, or mastoid infection.

Fungal specific risk factors include altered immune capabilities, broad-spectrum antibacterial therapy, and long-term indwelling foreign material. As more children experience iatrogenic prolonged neutropenia or cell-mediated suppression, more invasive fungal nervous system infections are likely.

Etiology

Gram-positive cocci dominate as brain abscess pathogens. The *Streptococcus milleri* group (*S. constellatus, S. intermedius,* and *S. anginosus)* comprise 50% to 70%, and staphylococci account for 10%

to 30%. Although *Streptococcus pneumoniae* causes meningitis, it rarely causes brain abscess.[1] Up to 30% of brain abscesses are polymicrobial, often including nutritionally variant streptococci (e.g., *Abiotrophia* species[2]) or anaerobes (e.g., *Bacteroides, Prevotella,* or *Peptostreptococcus* spp.). Detection of anaerobes often requires anaerobic culture methods.[3]

Gram-negative bacteria comprise 10% to 25% of brain abscesses or subdural empyemas (Table 46.1), mostly in young infants.[4,5] *Citrobacter,*[6,7] *Salmonella,*[8] *Serratia,*[9] *Proteus,*[10] and *Cronobacter* species (previously *Enterobacter sakazakii*)[11] and *Bacteroides fragilis*[12] are most frequent. *C. sakazakii* (associated with powdered formula) and *Citrobacter koseri* cause multifocal brain abscesses.

TABLE 46.1

Likelihood (Percentage of Cases) of Bacterial Pathogen in Focal Suppurative Nervous System Infections

Bacteria	Brain Abscess	Subdural Empyema	Epidural Abscess	
			Cranial	Spinal
Mixed	20–40	5–10	5–10	5–10
Alpha streptococci, not pneumococcus[a]	50–70	20–30	40–60	5–10
Anaerobic bacteria[b]	20–30[b]	5–10[b]	10–20	5–10
Staphylococci	10–30	10–20	10–20	60–80
Enterobacteriaceae	10–25	5–10	5–15	5–20
Pathogens of meningitis[c]	5–10	30–50	5–10	<1
Sterile[d]	10–25	20–30	20–30	5–10

[a] Aerobic, anaerobic, or microaerophilic (e.g., *Streptococcus anginosus* group).

[b] Mostly anaerobic streptococci.

[c] *Streptococcus pneumoniae, Haemophilus influenzae* type b, or *Neisseria meningitidis.* Much less common in countries with routine use of pediatric conjugate vaccines.

[d] More common with antibiotic pretreatment or in children

Chronic middle-ear infections, uncontrolled diabetes mellitus, and chemotherapy-induced neutropenia are risks for *Pseudomonas aeruginosa*.[13] Impaired cell-mediated immune function, such as, macrophage- or T-lymphocyte–related defects, or neutrophil phagocytic defects predispose to *Listeria monocytogenes*[14] or *Nocardia* spp.[15]

Fungal brain abscesses occur with congenital or acquired neutrophil abnormalities, stem cell[16] or solid organ transplantation,[17] or poorly controlled AIDS, particularly after broad-spectrum antibacterial treatment. More than 90% of brain abscesses after bone marrow or stem cell transplantation are due to fungi, usually *Candida* or *Aspergillus* spp.[18] In premature infants, *Candida* spp. increasingly cause multiple small brain abscesses.[19]

Although *Cryptococcus* usually manifests as meningitis, it can cause brain abscess. Other fungi rarely causing brain abscess include *Blastomyces,*[20] *Histoplasma,*[21] *Pseudallescheria,*[22] Zygomycetes,[23] *Coccidioides,*[24] *Dactylaria, Fonsecaea, Ramichloridium, Bipolaris, Exophiala, Curvularia,* and *Xylohypha (Cladosporium)* spp.

Protozoa causing brain abscess include *Acanthamoeba, Schistosoma,* or *Paragonimus* spp. With poorly controlled HIV, *Toxoplasma gondii* rarely causes brain abscess in children[25] but is more common in adults. *Entamoeba histolytica* brain abscess is rare even with amebiasis. Helminthic migration (*Strongyloides stercoralis, Trichinella* or *Taenia* spp.) can cause brain abscesses or masses.[26] Neurocysticercosis relatively frequently causes single or multiple, often ring-enhancing, central nervous system (CNS) masses among people from endemic areas (e.g., Mexico) and can be misconstrued as bacterial brain abscesses.

Table 46.2 includes additional uncommon pathogens.[27–30] Rarely, *Mycoplasma* or *Ureaplasma* spp. are causal.[31] *Mycobacterium tuberculosis* brain abscess[32] differs from tuberculoma, a granulomatous mass containing epithelioid and giant cells. Tuberculous abscesses are purulent collections containing acid-fast bacilli. Magnetic resonance imaging (MRI) differentiates these two conditions.

TABLE 46.2

Uncommon Pathogens in Brain Abscesses or Focal Ring Enhancing Lesions

Bacteria		Fungi	Parasites
Aerobic	**Anaerobic**		
Aggregatibacter aphrophilus	*Propionibacterium*	*Mucormycosis*	*Taenia solium*
Streptococcus pneumoniae	*Fusobacterium*	*Pseudallescheria boydii*	*Toxoplasma*
Eikenella	*Peptostreptococcus*	*Scedosporium*	*Entamoeba*
Enterococcus	*Bacteroides*	*Curvularia*	*Schistosoma*
Moraxella	*Clostridium*	*Histoplasma*	*Trichinella*
Pasteurella	*Actinomyces*	*Blastomyces*	*Strongyloides*
Bacillus cereus		*Coccidioides*	*Paragonimus*

Nocardia		*Cladosporium*	*Acanthamoeba*
Streptococcus pyogenes[a]			
Listeria			
Brucella[b]			

[a] *Streptococcus pyogenes* usually concurrent with acute mastoiditis.

[b] *Brucella melitensis* occurs mostly in the Middle East and Mediterranean areas.

Lesion location or distribution can suggest the pathogen. Frontal lobe abscess (usually a complication of sinusitis) suggests oral flora, that is, *Streptococcus* spp. (aerobic, microaerophilic, anaerobic), staphylococci, or anaerobic bacteria[33] (Table 46.3). Penetrating trauma increases the risk for *Staphylococcus aureus* (often methicillin-resistant *S. aureus* [MRSA]), but *Streptococcus* spp. remain more common. Temporal lobe or cerebellar abscesses suggest middle-ear or external-ear pathogens in addition to oral flora (mostly anaerobic or microaerophilic streptococci plus other anaerobes, and less often Enterobacteriaceae or *Pseudomonas* spp.).

TABLE 46.3

Relative Importance of Organisms by Site of Focal Lesion

Site	Most Common Pathogens
SOLITARY LESION	
Frontal lobe with sinusitis or oral/dental infection	Oral and/or nasopharyngeal aerobic and/or anaerobic flora, e.g., streptococci, *S. aureus*
Temporal lobe area, posterior fossa, or cerebellum contiguous with middle-ear/mastoid infection	Streptococci (aerobic and anaerobic), anaerobic oral flora, Enterobacteriaceae
Posttrauma	*S. aureus,* nonpneumococcal alpha streptococci, *Propionibacterium,* Enterobacteriaceae
MULTIPLE LESIONS	
Underlying congenital heart disease	Nonpneumococcal α-streptococci (aerobic and/or anaerobic), *Haemophilus* spp.
With endocarditis	Nonpneumococcal α-streptococci, *S. aureus*
With lung infection	Oral flora including anaerobes, *Nocardia* spp.
No known risk	*Staphylococcus aureus*
Immunocompromised host	*Toxoplasma,* fungi, *Nocardia* spp., Enterobacteriaceae

Hematogenous spread due to endocarditis, septic thrombophlebitis, lung abscess, pleural empyema, bronchiectasis (in cystic fibrosis), osteomyelitis, or skin infections classically produces multiple lesions in the distribution of the middle cerebral artery. However, hematogenous abscesses can produce any pattern.

Common hematogenous pathogens are *S. aureus,* aerobic or anaerobic streptococci, and rarely, *Candida, Nocardia,* or *Actinomyces* spp. With CCHD, *Aggregatibacter* (formerly *Haemophilus*) *aphrophilus* (an AACEK, formerly HACEK organism) is relatively common[34]; in contrast, *S. aureus* is more frequent with prosthetic valve endocarditis or prolonged bloodstream infection (de novo or associated with intravascular catheter).

Clues to pathogens in subdural empyemas relate to the pathogenesis. In young children, subdural empyema usually accompanies bacterial meningitis, a less frequent condition in countries with universal use of conjugate vaccines for the three major pathogens, that is, *Haemophilus influenzae* type b, pneumococcus, or meningococcus[35,36] (see Table 46.2).

Subdural empyemas not accompanying meningitis result from the same pathogens as brain abscesses. Aerobic and anaerobic streptococci (e.g., *S. intermedius* and *S. anginosus* group) predominate when associated with sinusitis. *S. aureus* is more common postoperatively or after trauma but can occur when associated with sinus or middle-ear infection. Cultures are sterile in 20% to 30%, likely owing to antibacterial pretreatment, nonviability of fastidious or anaerobic bacteria, or nonoptimal collection, transportation, and isolation procedures.[37]

Rare subdural pathogens include nontyphoidal *Salmonella,*[38] *S. pyogenes,*[39] *Burkholderia,*[40] *Brucella melitensis,*[41] *Propionibacterium,*[42] *Prevotella,*[43] fungi (e.g., *Candida albicans,*[44] *Pseudallescheria boydii*),[45] or *Mycobacterium tuberculosis*.[46] Gram-negative organisms are increasingly detected in both subdural empyema and epidural abscess.[47]

S. aureus is the most common pathogen causing both cranial and spinal epidural abscess.[48,49] However, *S. pneumoniae*[50] or *S. agalactiae*[51] also cause cranial epidural abscesses. *Pseudallescheria,*[45] *Aspergillus,*[52,53] or *Candida* spp.,[54] Zygomycetes, or *M. tuberculosis* can cause cranial epidural abscess in immunocompromised hosts.[55] Spinal epidural abscess rarely is due to *Brucella melitensis* (Middle Eastern and Mediterranean area),[56] *Nocardia asteroides* group,[57] *Actinomyces israelii,*[58] *Cryptococcus neoformans,*[59] or *Aspergillus* spp.[60] Epidural and other paravertebral abscess can complicate *Bartonella henselae* vertebral osteomyelitis.[61,62]

Septic intracranial thrombophlebitis most often is associated with sinusitis, mastoiditis, or facial infections (*S. pneumoniae,*[63,64] *S.*

pyogenes, or *S. aureus)*. Other otopathogens or non−group A streptococci also are reported.[61] Anaerobes (e.g., *Fusobacterium* spp.[65]) are infrequent causes, especially associated with Lemierre disease, which appears to have increased in frequency since 2005 and can have severe complications. Polymicrobial infections can occur.[66,67]

Epidemiology

Brain abscess is uncommon in developed countries but remains relatively common among socioeconomically disadvantaged people in developing countries. Risks vary geographically; for example, chronic otitis media is the primary risk in 60% of brain abscesses in China,[68] but only 30% in Europe.[69] Overall, nearly 25% of brain abscesses occur before 15 years of age, peaking between 4 and 7 years of age. Neonatal brain abscesses are associated most often with gram-negative bacterial meningitis. In immunocompetent hosts, most brain abscesses are solitary. Multiple brain abscesses are more frequent from hematogenous spread and occur in neonates or in immune-compromised patients.[70] Brain abscesses are multiloculated in 10% to 20% of immunocompetent hosts.

For intracranial subdural empyema, males predominate (3:1) among older children. The incidence by sex is neutral in young children.[71] In older children, the source is paranasal sinuses or middle ear or mastoid in about 85% and is hematogenous in 5% to 10%. Intracranial subdural empyema after neurosurgical procedures (e.g., craniotomy) is infrequent (0.04%).[47]

Spinal subdural abscess is rare in children,[72] with obesity as a possible risk factor.

Intracranial epidural abscess is the most common CNS suppurative complication of middle-ear, mastoid, or temporal bone infection. Posterior fossa epidural abscesses are extensions from the middle-ear or mastoid infection after osseous erosion of the petrous pyramid or over the sigmoid sinus plate.[73] Intracranial epidural abscesses also result from orbital abscesses or frontal sinusitis via valveless emissary veins or are concurrent with subdural empyema or cavernous sinus thrombosis.[74] Intracranial epidural abscess is 10 to 40 times more frequent than intracranial subdural empyema after neurosurgical procedures but still is uncommon (0.43%−1.8% of procedures).[47]

Spinal epidural abscess accounts for 6 out of 100,000 hospital admissions,[75] with fewer than 100 reported pediatric cases,[76] the largest series being 58 cases.[50]

Suppurative intracranial thrombophlebitis usually accompanies another intracranial infection, usually extradural, as a complication of mastoiditis or paranasal sinusitis. However, 10% to 20% of cases originate from facial (typically the middle third), dental, or neck infections.

Pathogenesis

Brain Abscess

A hematogenous source was traditionally most common, usually related to CCHD (Box 46.1). Among patients with unrepaired CCHD, 6% develop brain abscess. Brain infarction or emboli lead to infection, the risk increasing with time until repair. Right-to-left shunting, including through patent foramen ovale,[77] allows transiently circulating pathogens to bypass the reticuloendothelial filter in the lung. Classically, uncorrected tetralogy of Fallot or transposition of the great vessels was the most common anomaly predisposing to brain abscesses, but fewer now occur (about 28% overall),[78] owing to routine early surgical repair.

Box 46.1

Risk Factors for Brain Abscess[a]

Hematogenous (Approximately 30%)

Uncorrected cyanotic congenital heart disease

Septic thrombophlebitis

Lung infections, bronchiectasis

Cystic fibrosis[75]

Esophageal/rectal dilation or endoscopy[b,77]

Hereditary hemorrhagic telangiectasia

Pulmonary arteriovenous malformation[77]

Hepatopulmonary syndrome[78]

Septic abortion[80]

Contiguous Spread (Approximately 40%)

Middle-ear and/or mastoid infection

Sinusitis

Meningitis

Other focal infections (e.g., teeth, orbit, bone)

Penetrating head trauma

Ventriculoperitoneal shunt infection[89]

Postoperative intracranial surgery

Halo device to immobilize cervical spine[8]

UNKNOWN SOURCE (approximately 30%)

---

[a] Under "Hematogenous" and "Contiguous Spread," conditions are listed in order by relative frequency.

[b] It is unclear whether some infections result from direct spread from mucosal site via local drainage through the Batson plexus.

Endocarditis (especially acute left-sided) predisposes to brain abscess because septic embolization is more common. Increased magnitude and duration of bacteremias increase the risk for CNS infection. Septic embolization from deep neck phlebitis associated with parapharyngeal infection (Lemierre disease) produces brain abscess, often polymicrobial, with oral and anaerobic flora, especially *Fusobacterium* spp.[79] Brain abscesses also occur by hematogenous seeding from distant pyogenic infections, including bone, teeth, skin, and abdomen infections, chronic lung abscess, empyema, and bronchiectasis.[80]

Chronic pyogenic lung disease, such as associated with immunoglobulin deficiency or bronchiectasis from longstanding cystic fibrosis, increases the risk for brain abscess.[81] Rarely, brain abscess occurs with pulmonary arteriovenous malformations,[82] aspirated foreign body, or hepatopulmonary syndrome.[83] Endoscopy-associated brain abscess results from intestinal bacteria translocating to paravertebral veins and from there into the cavernous sinus.[84] Septic abortion and in situ intrauterine devices are associated with brain abscess.[85]

Extension from nearby infection (middle-ear, mastoid, sinus, orbit, face, or scalp) is now the most common cause of brain abscess (about 36%).[78] Extension from middle ear predominates in young children and from paranasal sinuses in male adolescents.[86–88] In teenagers, frontal, ethmoid, and sphenoid sinuses have thin bony or cartilaginous walls abutting the dura, allowing erosion (osteomyelitis) and ingress into the CNS. Other portals include preexisting or posttraumatic anatomic cranial openings or diploic or emissary veins.

Bacterial meningitis rarely causes brain abscess except in neonates. Thrombophlebitis, venous stasis, or ischemia likely contributes to the pathogenesis. Focal deep cerebritis, deep infarcts, and pathogen virulence (e.g., *S. aureus* or *Cronobacter*) appear important for brain abscess formation. Rarely, pyogenic infection between the lateral ventricles occurs because of anatomic communication with the ventricular system.[89]

Postoperative or posttraumatic brain abscess is uncommon (about 9%.).[78] However, reimplantation of bone flaps,[90] penetrating skull injuries (e.g., dog bite,[91] pencil,[92] or lawn dart puncture[93]), or open skull fracture increase the risk. Oral flora can penetrate through intraoral punctures (e.g., chopstick, umbrella).[94] Gut-associated ascending infection along a ventriculoperitoneal shunt or an untreated shunt infection can lead to brain abscess.[95] Other rare causes are orthopedic halo-pin device[96] or intracranial migration of foreign body (e.g., cervical spinal sublaminar or interspinous wire).[97] Preexisting intracerebral hematoma, necrosis, or neoplasm rarely can serve as the nidus of infection.

Subdural Empyema

In young children, subdural empyema can follow meningitis. In older children subdural empyema usually results from extracranial infection (e.g., middle ear, sinus, or calvarium).[35] Risk increases with postmastoidectomy bone defects, prior craniotomy,[37] skull trauma,[37] septic phlebitis of emissary veins,[87] ventriculoperitoneal shunt,[95,98] preexisting hematoma,[99] halo-pin traction,[100] bloodstream infection from lung abscess, or endoscopic procedures.[101]

Epidural Abscess

Intracranial epidural abscesses usually extend from infected sinuses,[102] middle ear, or orbit, but rarely result from penetrating head injuries, fetal monitoring,[103] or wrestling injury.[104] Tightly adhering dura usually impedes expansion of epidural abscesses, causing insidious clinical presentations. Epidural abscesses can extend (e.g., to the subdural space, brain), causing coexistent intracranial infections. MRSA is observed in epidural abscesses associated with deep lower extremity or pelvic septic venous thrombosis.[105]

Spinal epidural abscesses usually are hematogenous (e.g., from infected skin, soft tissue, bone, respiratory or urinary tract infection). Other sources are nearby infections (bacterial meningitis, osteomyelitis or retropharyngeal, retroperitoneal, or abdominal abscess); iatrogenic introductions (after spinal fracture,[106] penetrating injury, spinal surgery, spinal fusion, spinal rod placement, lumbar puncture, steroid injection,[107] or epidural analgesia[108]); fistulas (Crohn disease),[109] midline neuroectodermal defect, dermal sinus; or intradural tumor (e.g., lipoma). Almost one third of epidural abscesses have no identified source.

Intracranial Septic Venous Thrombosis

Intracranial septic thrombosis also follows bacterial meningitis (especially superior sagittal sinus) or arises from contiguous infections (sinuses, ear, face, or oropharynx) through emissary veins.[110] Lateral venous sinus involvement usually is otogenic, but cavernous sinus thromboses originate from teeth, paranasal or sphenoid sinuses, or face.[111] Septic venous sinus thrombosis can occur near an epidural abscess or by hematogenous spread.

Increased risk for nonseptic thrombosis occurs with sickle cell disease, dehydration, or malignancies.

Clinical Manifestations

Brain Abscess

Abscess location affects presenting signs and symptoms (Box 46.2). Frontal lobe abscesses may have prolonged asymptomatic periods, producing symptoms and signs only when mass effect increases intracranial pressure (ICP). Parietal lobe abscesses often remain silent until extending to the sensorimotor cerebral cortex. Pathogen virulence and host immune status also affect the clinical acuity. Although the mean duration of bacterial brain abscess symptoms before diagnosis is 2 weeks, range is up to 4 months.[4]

Box 46.2

Signs and Symptoms in Relation to Site of Brain Abscess

Any Site

Signs of increased intracranial pressure (often late signs)

- Headache, nausea, emesis, papilledema
- Depressed consciousness

Behavioral changes

- Confusion, decreased attentiveness

Frontal Lobe

Behavioral changes

- Personality changes, emotional lability, impulsive behavior

Motor abnormalities

- Motor speech disorder (apraxia), forced grasping and sucking
- Focal weakness, hemiparesis

Temporal Lobe

General

- Ipsilateral headache

Cranial nerve dysfunction

- Upper homonymous hemianopia, ipsilateral third cranial nerve palsy

Motor abnormalities

- Speech dyspraxia, aphasia[a]
- Motor dysfunction of face and arm

Parietal Lobe

Visual abnormalities

- Homonymous hemianopia, visual field defects in inferior quadrant

Motor abnormalities

- Dysphasia,[a] speech dyspraxia[b]

Perceptive abnormalities

- Contralateral spatial neglect[b]

Intrasellar

Visual field defects

Endocrine imbalance via altered pituitary function

Cerebellar

Balance/perception abnormalities

- Lateral nystagmus (fast component toward lesion)
- Dizziness or central vertigo, ipsilateral ataxia, tremor
- Vomiting aggravated by motion

Cranial nerve dysfunction

- Sixth cranial nerve palsy

Brainstem

Dysphasia

Facial and multiple cranial nerve palsies

Hemiparesis

---

[a] If abscess is in dominant hemisphere.

[b] If abscess is in nondominant hemisphere.

The initial presentation of brain abscess in about 50% of cases includes headache, fever, and vomiting (Table 46.4). Mental status changes or generalized seizures occur in fewer than 50% of cases of brain abscess. Lateralized headache in children increases risk for organic intracranial pathology. Focal neurologic abnormalities occur in 35% to 40%. Papilledema and meningismus occur in 30% of affected children. Coma, a late sign, occurs in 15% to 20%.

TABLE 46.4

Clinical Manifestations of Focal Suppurative Infections of the Central Nervous System by Percentage of Cases

Signs or Symptoms	Brain Abscess (%)	Subdural Empyema (%)	Cranial Epidural Abscess (%)	Septic Venous Thrombosis		
				Superior (%)	Lateral (%)	Cavernous (%)
Headache	60–70	60–80	100	70–90	80–90	75–90
Emesis	50–60	60–70	20–30	50–80	60–80	30–50
Fever	40–60	80–90	80–90	60–70	75–90	70–85
Focal neurologic deficit	35–50	30–40	10–20	40–60	60–75	75–90
Mental status change	30–40	60–80	50–60	55–75	20–45	15–30
Papilledema (usually late)	30–40	35–50	<5	40–60	25–40	65–80
Seizures	25–40	50–60	20–30	50–60	15–25	15–25
Meningeal signs	25–35	50–60	10–20	60–70	30–40	25–40
Hemiparesis	20–30	60–70	15–30	45–55	<5	<5
Coma	15–20	20–30	<5	60–80	25–45	10–15

The classic triad (fever, headache, and focal neurologic deficit) suggesting brain abscess occurs in fewer than 30%. Most pediatric brain abscesses have nonspecific clinical presentations that must be distinguished from other CNS processes (Table 46.5). Sudden clinical deterioration with meningismus suggests rupture of abscess into the ventricles or subarachnoid space.[112]

TABLE 46.5

Differential Diagnosis of Brain Abscess

Infectious Etiologies	Noninfectious Etiologies	
	Vascular	**Other**
Meningitis	Hemorrhage	Primary tumor
Encephalitis[a]	Parenchymal	Metastatic tumor
Meningoencephalitis	Intracerebral	Multiple sclerosis
Subdural empyema	Subarachnoid	Acute disseminated encephalomyelitis (ADEM)
Mycotic aneurysm[b]	Subdural (chronic)	
Epidural abscess	Venous sinus thrombosis[d]	

Cranial osteomyelitis Suppurative thrombosis Cysticercosis Tuberculoma[c] Cryptococcosis	Cerebral infarction	
	Migraine	
	Central nervous system vasculitis	

[a] Especially when the etiologic agent is herpes simplex virus.

[b] As a result of septic embolus (e.g., endocarditis).

[c] Or tuberculous abscess.

[d] Nonseptic.

Intracranial Subdural Empyema

In infants, subdural empyema can evolve during appropriate antimicrobial meningitis therapy as bulging fontanel, persistent fever beyond 5 days of treatment, or new onset of neurologic findings (e.g., depressed responsiveness, seizures). Persistent febrile meningismus also suggests subdural empyema.[37,113] Signs of increased ICP (vomiting, depressed responsiveness, enlarging head circumference, or papilledema) warrant investigation for subdural empyema.[114]

In older children, subdural empyema mimics brain abscess, with fever or vomiting, or both, but often occurs without headache. Diagnosis can be delayed until onset of hemiparesis or hemiplegia. After surgery or trauma, an overlying wound infection with occurrence of focal neurologic signs suggests subdural empyema.

Intracranial Epidural Abscess

Onset is insidious, with nonspecific symptoms (fever, headache, and mental status changes, sometimes with localized pain or tenderness,). Additional signs that are common in other intracranial suppurative processes (vomiting, seizures, focal neurologic deficits, papilledema, or meningeal signs) are relatively rare, developing only if mass effect or increased ICP occurs.

Unilateral facial pain with weakness of the ipsilateral ocular rectus muscle (Gradenigo syndrome) indicates an epidural abscess near the petrous bone. Confusion progressing rapidly to coma with focal or generalized seizures (symptoms of obstructed superior sagittal sinus) suggests an occipital epidural abscess.

S. aureus, particularly MRSA, is the most common pathogen in epidural abscesses accompanying orbital cellulitis and acute sinusitis.[115]

Spinal Epidural or Subdural Abscess

Initially, spinal epidural abscess[116] manifests as localized or generalized back or flank pain exaggerated by movement, particularly spinal rotation. Local edema or tenderness to percussion can develop, followed by nerve root pain, which assist in abscess localization. Focal neurologic deficits (usually sensory and motor) develop early, progressing to weakness and impaired sensation. Signs then progress to paraparesis, bladder or bowel dysfunction, or altered consciousness. Early intervention prevents paralysis or paraplegia, which can occur in as few as 4 days from onset of nerve root pain or one week from initial back pain.[117]

Spinal subdural abscess manifests similarly to epidural abscess but can be differentiated by meningismus without focal spine tenderness to percussion.

Septic Venous Thrombosis

Clinical presentations vary based on the involved venous sinus. Complete thrombosis plus obstruction of blood flow in superior sagittal sinuses commonly presents as severe generalized or frontal headache. Soon nausea, vomiting, and meningismus develop, sometimes progressing rapidly to coma. Focal or generalized seizures or hemiparesis can occur. If venous obstruction is incomplete, symptoms are less severe and progress more slowly.

Cavernous sinus thrombosis is more frequent in teenage males, manifesting as cranial nerve deficits (usually III and VI) plus prominent headache often localizing to the orbit or second branch of the trigeminal nerve. Unilateral periorbital edema quickly becomes bilateral.[111] Ptosis with ophthalmoplegia can cause impaired vision or blindness. Papilledema or retinal venous dilation occurs in 50% and meningismus in up to 33% of cases.

Septic thrombosis of lateral sinuses manifests subacutely, usually with temporal or occipital headache, followed by nausea, vomiting, or vertigo. The otogenic source often is detected by middle-ear examination (e.g., ruptured tympanic membrane, cholesteatoma). Meningismus is less frequent than with cavernous sinus thrombosis, but altered mental status is more common. Gradenigo syndrome or any soft tissue swelling behind the auricle (Griesinger sign) raises suspicion for lateral sinus thrombosis.

Caveat With Extracranial Infections

Despite obvious extracranial infections, concurrent occult intracranial foci also can be present, such as with orbital suppurative complications of sinusitis.[33,118] Multifocal intracranial or parameningeal CNS infections are not uncommon (e.g., subdural empyema or brain abscess accompanying meningitis). Rapidly progressing symptoms, change in neurologic status, or poor response after antimicrobial therapy or surgical drainage of an orbital abscess suggests concurrent intracranial focus. Pott puffy tumor (with frontal sinusitis) (Fig. 46.1) requires imaging to assess for intracranial suppurative foci.[119]

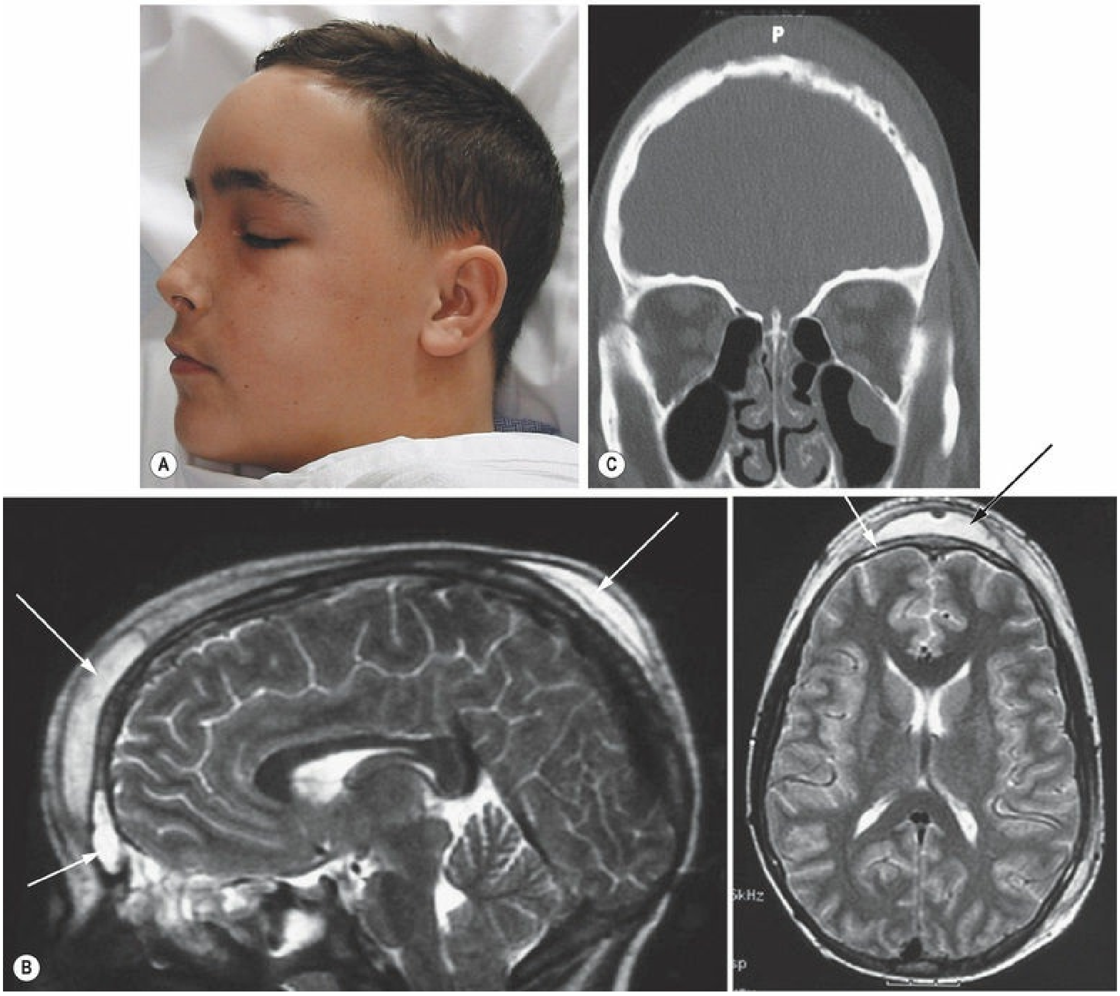

FIGURE 46.1 A 14-year-old presents with 1 week of high fever and chills, followed by facial and forehead pain and swelling. There is an edematous, tender, fluctuant mass over the forehead and occiput (A). Computed tomography (CT) showed pansinusitis. Sagittal and axial, T_2-weighted magnetic resonance imaging (B) revealed increased signal in extracranial frontal and occipital masses *(long arrows),* the frontal sinus *(medium arrow),* and frontal bone *(short arrow).* Blood culture yielded *Fusobacterium necrophorum.* Coronal CT after drainage confirmed osteomyelitis of the frontal bone (C). Prolonged antibiotics yielded complete recovery. (Courtesy of E. D. Thompson and S. S. Long, St. Christopher's Hospital for Children, Philadelphia, PA.)

Differential Diagnosis

Brain Abscess

The differential diagnosis of brain abscess includes infectious and noninfectious conditions (see Table 46.5). Vascular and oncologic diagnoses are the most common noninfectious causes. Altered consciousness, seizures, headache, nausea, and emesis should raise suspicion for postinfectious acute disseminated encephalomyelitis.

Focal suppurative CNS infection should be considered when any three of the following are present: fever, headache, nausea or emesis, increased ICP, altered consciousness, seizures (focal or generalized), or cranial nerve abnormality. However, these CNS symptoms and signs also can reflect nonpurulent conditions, infectious or otherwise, that mimic purulent brain abscess.

Extracerebral Intracranial Infections

Differentiating among various extracerebral intracranial infections is difficult because signs and symptoms overlap and usually are nonspecific. The differential diagnosis of suppurative intracranial extracerebral infection resembles that of brain abscess; however, some signs may be more specific. Focal neurologic signs during confirmed bacterial meningitis warrant brain imaging for focal complications. Meningismus persisting more than 3 days into antibiotic therapy or an initial cerebrospinal fluid (CSF) not fully compatible with bacterial meningitis warrant search for a parameningeal suppurative focus. Persisting meningismus rarely indicates parenchymal brain abscess, except with rapid clinical deterioration due to abscess rupture into ventricles or parameningeal spaces.

Cranial epidural abscess can complicate infections outside the CNS (orbital abscess or phlegmon) or with the CNS (meningitis, brain abscess, venous thrombophlebitis, or subdural empyema). Thus delineating all foci requires neuroimaging.

The differential diagnosis of septic thrombosis of dural venous sinuses includes any cause of spontaneous, inflammatory, or posttraumatic thrombosis. These include disseminated intravascular coagulopathy, hypercoagulopathy (e.g., protein S and antithrombin III deficiency), polycythemia, sickle cell anemia, dehydration, congenital heart disease, malformation of the vein of Galen, nephrotic syndrome, use of oral contraceptives, pregnancy, trauma, neoplasm, asphyxia, brain infarction, and pseudotumor syndrome. Other intracranial infections, such as brain abscess, subdural empyema, and meningitis, also are possible causes of thrombosis. Cavernous sinus septic thrombosis can mimic orbital cellulitis or ophthalmoplegic migraine and often is accompanied by cranial nerve abnormalities.

Spinal Infections

Spinal epidural abscess or subdural empyema can mimic diskitis or syphilis (tabes dorsalis), or can complicate vertebral or spinal tuberculosis or vertebral osteomyelitis. Acute transverse myelitis, spinal cord tumor, lymphoma, hematoma in the epidural or subdural space or spine, and vascular malformation must be considered. Larger differential diagnoses can be found in two literature reviews.[120,121]

Laboratory Findings and Diagnosis

Routine Tests

Blood tests are generally nonspecific. Peripheral white blood cell counts are more than 10,000 cells/mm^3 in nearly 50% of children with brain abscess, but only 30% exceed 20,000/mm^3 and only 25% exhibit a left shift (band forms, >10%). The erythrocyte sedimentation rate (ESR) is insensitive, being normal in up to 40% of brain abscesses, particularly when associated with CCHD.[122] C-reactive protein (CRP) is more sensitive but is not specific.[123] Both ESR and CRP appear to be elevated more often when intracranial suppurative foci complicate sinusitis.[124] In spinal infection neither the ESR nor CRP is reliably abnormal.[125] Procalcitonin is not useful.

Blood cultures yield a pathogen in approximately 10% of cases of brain abscess.[3] Low-frequency delta waves on electroencephalogram are compatible with brain abscess.[4,126]

To prevent notable morbidity, brainstem herniation, or even death, increased ICP must be excluded by computed tomography (CT) or MRI before lumbar puncture when suspecting focal intracranial suppuration.[3]

Normal CSF occurs in up to 20% of brain abscesses. Elevated CSF protein (>40 mg/dL) occurs in 70% to 85%; mild to moderate pleocytosis (<500/mm^3) occurs in 60% to 80%, with neutrophil predominance in 40% to 60%. Hypoglycorrhachia (<40 mg/dL) occurs in fewer than one third. Positive CSF culture is uncommon (<10%) except with coexisting meningitis or rupture of brain abscess into subarachnoid spaces. Polymerase chain reaction testing of brain abscess material can provide rapid pathogen identification,[127] but is not widely available, and sensitivity and specificity are not defined fully. Testing for 16S recombinant RNA detects more species than are cultivatable in polymicrobial brain abscesses but is not standardized or available universally.[128]

CSF findings associated with spinal epidural abscess or subdural empyema are nonspecific, with normal to moderately elevated neutrophil and protein values. Lumbar puncture through infected lumbar tissue (e.g., spinal epidural abscess) can inadvertently inoculate CSF. Partially or completely obstructed CSF flow around the spinal cord from infection or tumor can elevate CSF protein concentration (>100 mg/dL), but usually CSF shows 100 to 300 white blood cells/mm^3 (mostly lymphocytes) and normal glucose concentrations.

Imaging Studies

Imaging of brain, sinuses, middle ears, and orbits is critical to identify intracranial infections, potential sources, and to formulate management.

Specific Considerations

Brain Abscess.

Use of contrast-enhanced CT or MRI reduces mortality rates from brain abscess by 90% because lesions are diagnosed earlier, localized more accurately, and surgically drained more safely and completely.

Contrast-enhanced CT shows enhanced vascularity related to inflammation.[129] Typically, a hypodense signal from brain tissue edema surrounds a bright ring of signal enhancement, which in turn surrounds a central hypodense signal of the abscess core (Fig. 46.2). Cerebritis can appear similarly but is not as well demarcated. CT findings can lag clinical manifestations by several days; an initially normal CT (particularly non−contrast-enhanced) does not exclude brain abscess. Further, neutropenia and corticosteroid therapy can diminish ring enhancement.[130] Tumor, granuloma, resolving hematoma, or infarct can produce ring enhancement.

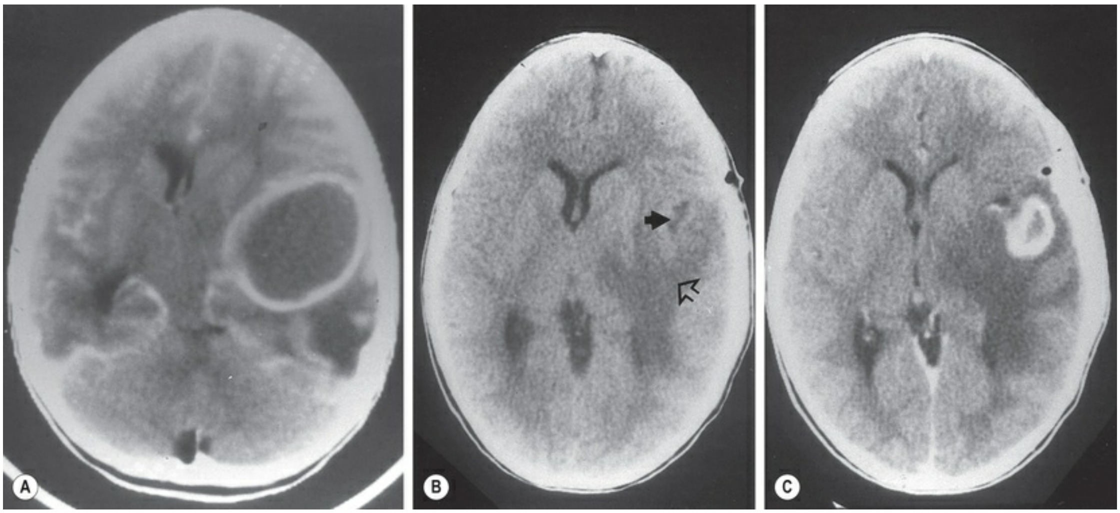

FIGURE 46.2 Computed tomography (CT) in a child with headache for 6 weeks and temporal lobe brain abscess. (A) CT with contrast at diagnosis shows intense ring enhancement and edema. (B) CT without contrast following surgical drainage shows a much smaller abscess cavity *(solid arrow).* Marked edema persists *(open arrow).* (C) Postsurgical contrasted CT reveals an abscess cavity with air, enhanced abscess wall, and marked edema. (Courtesy of M. A. Radkowski, MD, Children's Memorial Hospital, Chicago.)

Gadolinium-enhanced MRI may be superior to CT, revealing a peripherally enhancing lesion with enhanced signal on diffusion-weighted imaging (DWI). Experienced radiologists often can differentiate infectious from noninfectious lesions in the brain.[131,132]

Subdural Empyema.

Open fontanels may permit use of high-resolution ultrasonography to detect and differentiate subdural empyema from subdural effusion.[133] Intralesional particulate or shifting material suggest an empyema. CT is more specific and does not require an open fontanel. Non−contrast-enhanced CTs can demonstrate hypodense pus collections, but contrast-enhanced CT is superior at delineating the inflamed meninges or cerebral cortex (Fig. 46.3). Higher resolution of MRI makes MRI superior to CT for detecting smaller lesions, extra-axial fluid near bones, and rim enhancement.[134] Neither CT nor routine MRI always definitively distinguishes subdural empyema from reactive subdural effusion (the more common meningitis complication). DWI can improve characterization of subdural fluid.[135]

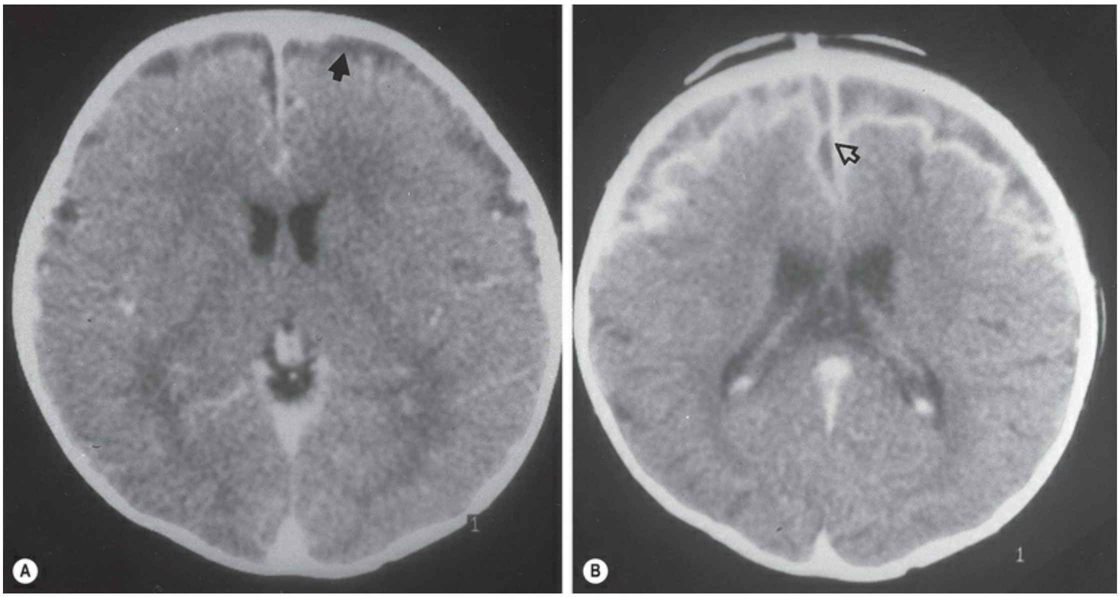

FIGURE 46.3 Computed tomography in an 8-month-old with meningitis and seizures during therapy (A) shows bilateral extra-axial fluid collections in the frontal region *(solid arrow),* suggesting early subdural empyema. (B) One week later, there is increased extra-axial fluid extending to the anterior interhemispheric fissure *(open arrow)* and enhanced membrane consistent with subdural empyema. (Courtesy of M. A. Radkowski, MD, Children's Memorial Hospital, Chicago.)

Epidural Abscess.

Cranial epidural abscesses show focal hypodense pus collections between dura and calvarium by CT. Contrast-enhanced CT shows enhanced rims around abscesses, displacing dura (Fig. 46.4). MRI reveals subdural abscesses in more detail and otherwise undetected concomitant epidural abscesses.

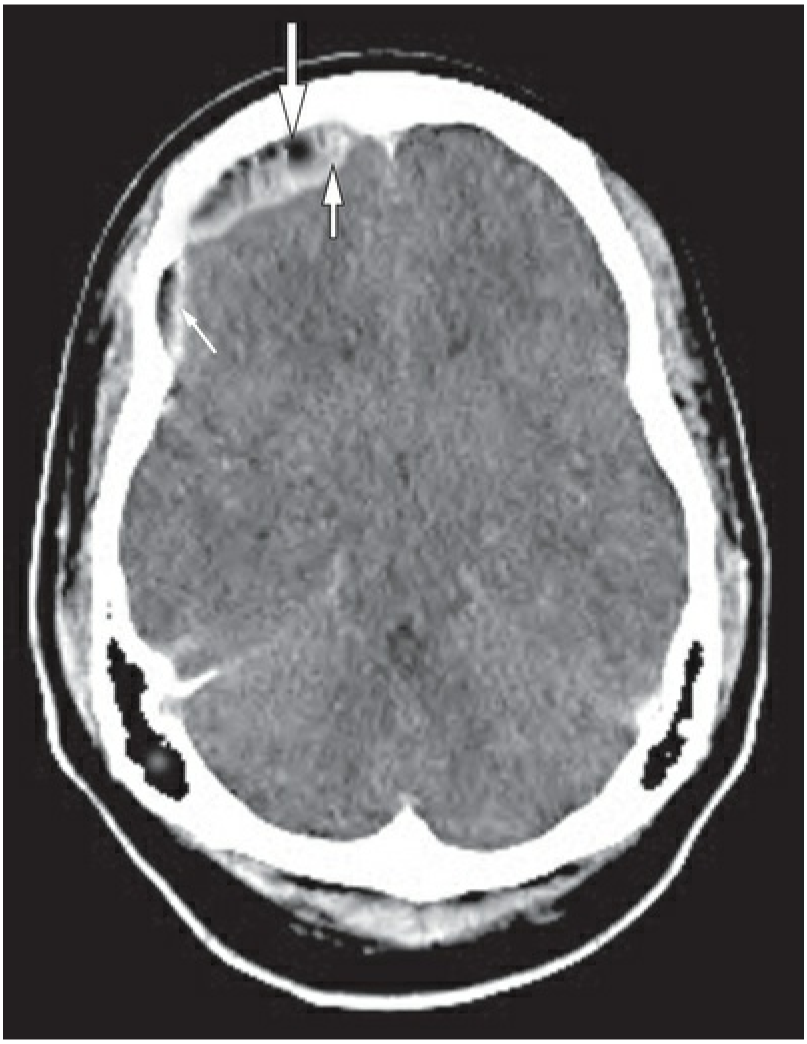

FIGURE 46.4 Contrast-enhanced computed tomography of a 16-year-old with sinusitis and persistent fever despite therapy shows collections in the frontal region *(large arrow),* which is relatively large and has epidural abscess, and subdural extension *(medium arrow).* There is an additional small extra-axial collection consistent with epidural abscess *(small arrow)* in the parietal area. (Courtesy of Lisa Lowe, MD, Children's Mercy Hospitals and Clinics, Kansas City, MO.)

Venous Sinus Thrombosis.

Sagittal venous sinus thromboses in infants can be detected by ultrasonography.[136] Filling defects in thrombosed sinuses are visible on contrast-enhanced CT. Superior sagittal sinus thrombosis appears as hypodense triangular areas surrounded by a hyperintense ring (the delta sign).[61] MRI is superior for detecting diminished venous flow (Fig. 46.5).

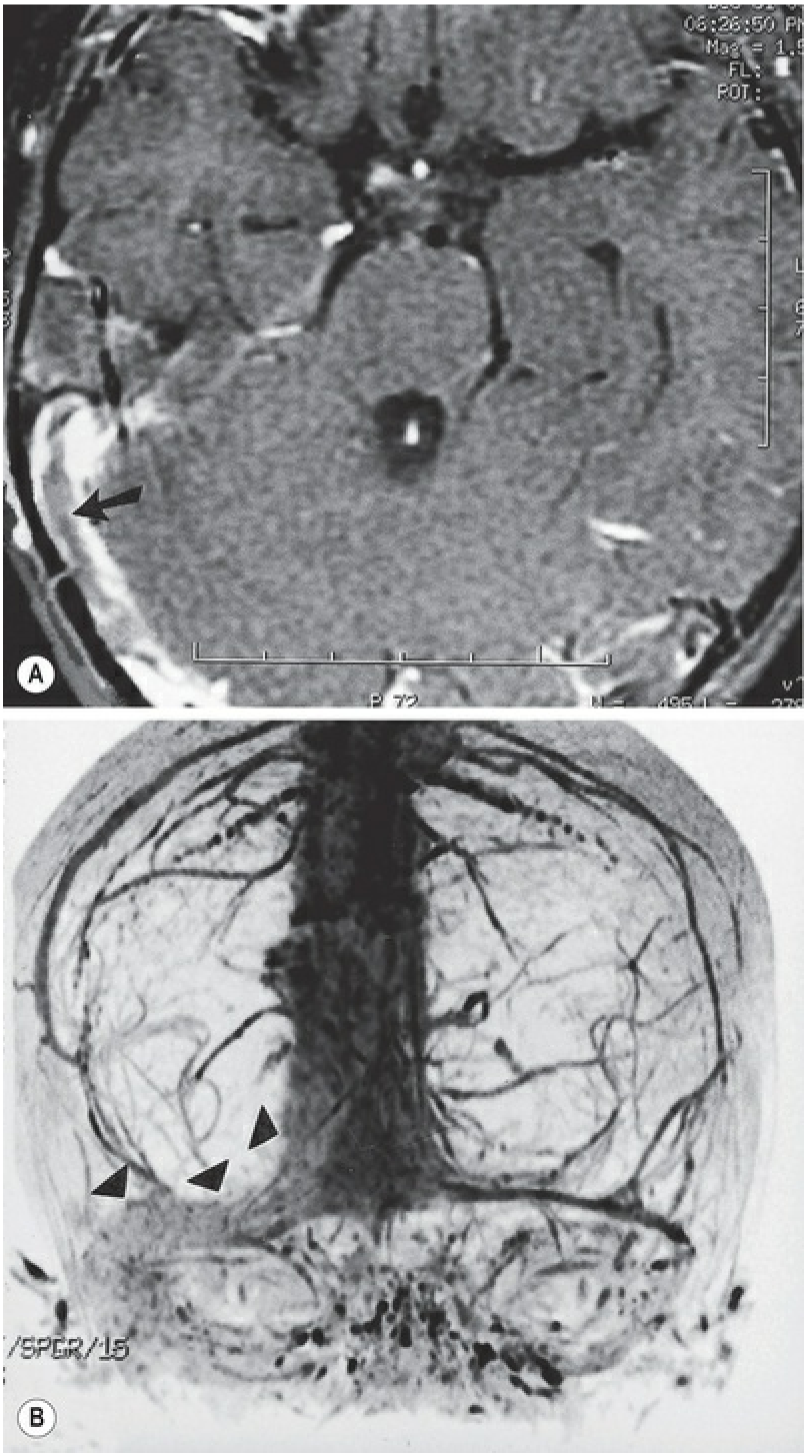

FIGURE 46.5 (A) T_1-weighted magnetic resonance imaging with contrast shows thrombosis of the transverse (lateral) sinus. The greyish area *(arrow)* represents the thrombus itself. (B) Three-dimensional, time-of-flight magnetic resonance angiography in the same patient shows complete blockage of the sinus, with extension of thrombus into the superior sagittal sinus *(arrowheads).* (A, Courtesy of C. Darling, MD, Children's Memorial Hospital, Chicago.)

General Considerations

MRI is the most sensitive routine diagnostic test currently available for intracranial suppurative infections because of superior soft tissue detail compared with CT.[137] Lesions are detected earlier, and smaller lesions undetectable by CT can be apparent. Contrast-enhanced CT with reconstructed coronal and sagittal planes extending through frontal bone and sella turcica can avoid missing suppurative processes (e.g., epidural or interhemispheric abscess) not seen with standard maxillofacial or orbital CT.

Contrast-enhanced MRI differentiates abscess fluid from CSF and is more accurate for detecting ruptured abscess.[138] If conventional and diffusion MRI does not differentiate abscess from cystic tumor, perfusion-weighted images may be useful. Because abscess capsules are hypovascular compared with tumor capsules, relative blood signal is different.[139] Although MRI is superior to CT for venous thrombosis and surrounding inflammation, magnetic resonance angiography can demonstrate diminished flow in occluded veins. Contrast-enhanced magnetic resonance venography can be helpful to discern dural venous thrombosis from artifact due to sluggish venous flow. Magnetic resonance spectroscopy also may distinguish bacterial brain abscess from necrotic brain tumor.[140]

MRI is superior to CT for epidural or subdural spinal abscesses, which typically are isointense on T_1-weighted images but hyperintense on T_2-weighted images. Concomitant diskitis, osteomyelitis, or paraspinal abscess is identified easily. Further, MRI differentiates active inflammation from chronic granulation. MRI also is superior in differentiating more common reactive subdural effusions from empyema, and subdural from epidural abscess. Because of intense radiation exposure from CT, MRI is preferred for follow-up, particularly if MRI was used initially.

Management

Medical-Surgical Management Versus Medical Therapy Alone

CT- or MRI-guided stereotactic techniques revolutionized management of intracranial suppurative infections,[141] being minimally invasive and performed using local anesthesia with minimal risk for hemorrhage or complications. Pathogen detection in aspirates using Gram, acid-fast, India ink, or specialized immunohistochemical stains as well as by aerobic or anaerobic, fungal, and mycobacterial culture allows specific antimicrobial therapy. New molecular methodologies allow detection of nucleic acids from nonviable organisms.[142]

Brain Abscess

Antibiotic therapy plus open surgical drainage has been standard management. However, antimicrobial therapy without aspiration or surgery is preferred (1) when concomitant bacterial meningitis is due to a confirmed pathogen; (2) when abscess is deep seated or in critical or high-risk anatomic sites; or (3) for poor surgical candidates. Medical-only therapy, even in ideal candidates, can fail. Follow-up is necessary, with repeated imaging if signs and symptoms do not resolve as expected or if deterioration occurs. Reduced ring enhancement, less edema, and less mass effect generally occur within 1 to 2 weeks of initiating therapy when patients respond favorably to medical-only management. Reduced abscess size usually occurs within 2 to 4 weeks.

Antibiotics plus lesion aspiration are successful with small (<3 cm), well-encapsulated brain abscesses in alert, clinically stable patients without signs of increased ICP.[143] It may not be possible to sample each of multiple abscesses, but culture of aspirated material from at least one abscess by CT- or MRI-directed stereotactic technique should be helpful.

Antibiotic susceptibilities of pathogens from blood (10% or less of patients), CSF culture (<10% of patients), or imaging-guided aspiration of abscess material (65%) improve likelihood of treatment success in the absence of open surgery.

Patients with large abscesses and those who are failing medical-only management require either closed stereotactic aspirational drainage or craniotomy (hopefully with excision). Disadvantages of stereotactic aspiration can be the need in some cases for repeated aspirations (leading possibly to more tissue damage or bleeding) and the relative inaccessibility of posterior fossa lesions. Excision is preferred for (1) fungal or helminthic abscesses not responding to medical therapy; (2) posterior fossa abscesses, especially with coma or brainstem compression[144]; (3) failure to improve clinically or by imaging despite aspiration of multiloculated abscesses; or (4) reaccumulation after repeated aspirations.[145]

Cure rates of more than 90% result from combining (1) surgical aspiration or removal of all abscesses greater than 2.5 cm in diameter; (2) 6 weeks or longer of effective antibiotic therapy; and (3) repeat neuroimaging to ensure abscess cavity resolution before cessation of antibiotics.[144,146]

Decision on duration of therapy, as well as intravenous versus oral formulations, is individualized. Antibiotics are continued for 3 to 6 weeks with the expectation of improvement of clinical and imaging findings. The shorter 3- to 4-week course is reasonable if complete surgical excision of the brain abscess is possible.[147] The mean time to normalization of CRP values if elevated is about 3 weeks.[146] Follow-up imaging studies near the end of the proposed treatment duration should provide evidence of lesion improvement before stopping therapy and provide a baseline in the case of later symptoms and signs suggesting relapse. The end point of therapy should be resolution of the abscess cavity, not absence of enhanced signal. Repeat imaging in asymptomatic patients beyond this is not necessary and can be misleading because enhanced signal persists beyond resolution of infection.

Corticosteroid treatment for brain abscess is controversial and is used infrequently because of potential disadvantages, including reduced antibiotic penetration through the steroid-stabilized blood-brain barrier. However, small series have not shown increased mortality, or significant outcome differences, related to corticosteroid use.[148] Corticosteroids directly decrease ring enhancement out of proportion to improvement in infection, and "rebound" of enhancement can occur on discontinuation, compromising interpretation of repeated imaging. Corticosteroids should be reserved for cases of severe or progressively increased ICP or neurologic deterioration, when reduction of edema may be lifesaving. A short course (3 to 6 days) of high-dose dexamethasone (0.4 to 2 mg/kg/day divided every 6 hours) generally is considered safe.

Extracerebral Abscesses

Antibiotics alone are sufficient for treatment of a small subdural empyema (<3 cm in diameter) or in neurologically stable patients rapidly responding to empiric therapy.[37,149] Management with appropriate antibiotic therapy plus aspiration of subdural empyema accompanying bacterial meningitis usually is sufficient as antimicrobial susceptibility of the pathogen is documented. Subdural empyema from other causes (e.g., contiguous site infection or after penetrating trauma) may not be aspirated easily, necessitating a bur hole or craniotomy. The empyema's location and extent dictate the type of drainage procedure. Although craniotomy provides better evacuation of pus from a larger empyema, bur hole plus irrigation can be effective.[150] Irrigating empyema cavities with antibiotics is not recommended or supported by current data. As little as 2 weeks of intravenous antibiotics can be sufficient in patients with subdural empyema completely drained by craniotomy.[151]

Unless cranial epidural abscess is less than 1 cm in diameter or close to critical structures making intervention dangerous, drainage and debridement plus appropriate antibiotic given systemically usually is performed, although there is increasing use of medical management with (or sometimes without) aspiration. For example, medical management appears adequate for isolated epidural abscesses with minimal mass effect, such as complicating sinusitis.[152–154] Repeat MRI should show reduced abscess size and absence of subdural extension. Decreased abscess size may not occur until after more than 2 weeks of therapy. Total antibiotic therapy for 3 to 4 weeks is adequate, except with concomitant osteomyelitis (when total therapy usually is 4 to 6 weeks).

In most cases of infection with suppurative complete venous thrombosis, appropriate antibiotic therapy plus surgical drainage of the suppurative source is performed.[111] Anticoagulant therapy is somewhat controversial because of the risk for hemorrhage[155] but is becoming standard, particularly with incompletely thrombosed obstruction of a lateral sinus. The risk for hemorrhage appears to be low in patients with no evidence of hemorrhagic complications by CT or MRI, and early anticoagulant treatment appears to be beneficial.[156] Internal jugular vein ligation is not necessary, but repeated MRI or CT monitoring for progression of thrombosis is important.

For spinal epidural or subdural abscess, urgent drainage and appropriate antibiotic therapy are critical to halting progressive permanent neurologic deficits. Endoscopic surgery is preferred to open laminectomy.[157] Antibiotics alone can be successful in patients with localized pain but without progression of root pain or evidence of spinal cord compression, or in patients who are stable for more than 3 days without radiculopathy or signs of partial cord compression.[158] Frequent MRI studies are important to document regression.

Antibiotic regimen for spinal epidural or subdural abscess should be designed to adequately penetrate to the site, and antibiotic generally is given for 3 to 4 weeks, unless osteomyelitis is present, in which case therapy may be as long as 8 weeks. The duration of intravenous antibiotics depends on the extent of the epidural or subdural abscess, accompanying foci of infection (e.g., myositis or osteomyelitis), and drug susceptibility of identified pathogens and bioavailability of oral forms of drug. Adequate CSF penetration is important with subdural abscesses, but is not as critical with epidural abscesses without a concomitant intradural or brain focus. Intravenous therapy for as few as 5 to 7 days can be effective if the pathogen and antimicrobial susceptibility are known; therapy can be completed using oral agents having sufficient bioavailability (e.g., fluoroquinolones, linezolid, clindamycin, rifampin).

Specific Antimicrobial Regimens

Recommended empiric antibiotics (Table 46.6) are based on likely pathogens, predisposing conditions, expected susceptibility patterns, and concentration of antibiotic at infected sites.[159] Recommendations are based on clinical experience or case series (mostly in adults) because there are no well-controlled pediatric trials.

TABLE 46.6

Empiric Therapy for Brain Abscess Based on Predisposing Factors

Predisposing Factor	Antibiotic (Dose)
Congenital heart disease	Vancomycin (60 mg/kg/day) *plus* ceftriaxone (100 mg/kg/day)[a] *plus* metronidazole (30 mg/kg/day)[b]

Dental pathology	Penicillin (300,000 U/kg/day) *plus* metronidazole[b] (as above); *or* Ampicillin-sulbactam (300–400 mg/kg/day)[c]
Sinusitis, mastoiditis, and/or otitis media[d,e]	Vancomycin (as above) *plus* ceftriaxone (as above)[a] *plus* metronidazole (as above)[b]
Penetrating trauma or postsurgery	Vancomycin (60 mg/kg/day) *plus* ceftriaxone (100 mg/kg/day)[a] or cefepime (150 mg/kg/day)
Meningitis	
Neonates	Cefotaxime (50 mg/kg/dose) *plus* ampicillin (100 mg/kg/dose) with dosing interval for each drug being q12h in first week of life, q8h from 8 to 28 days of life and q6h >28 days of life)
Infants and children	Ceftriaxone (as above)[a] *plus* vancomycin[b] (60 mg/kg/day)
Endocarditis	
Natural valve	Ampicillin[f] (as above) *plus* aminoglycoside (maximal doses); *or* Ceftriaxone (as above)[a] *plus* vancomycin (as above)
Prosthetic valve	Vancomycin (as above) *plus* gentamicin
Unknown or immunocompromised[g]	Vancomycin (as above) *plus* ceftazidime (see below) *plus* metronidazole

[a] Cefotaxime (300 mg/kg/day) can be substituted.

[b] If anaerobic bacteria are resistant to metronidazole and β-lactam, change to meropenem (120 mg/kg/day), or in countries where still available, use chloramphenicol (80–100 mg/kg/day).

[c] Ampicillin-sulbactam (≥300–400 mg/kg/day of ampicillin) acceptable only if methicillin-resistant *Staphylococcus aureus* or penicillin-resistant pneumococcus is not a risk.

[d] When staphylococci or penicillin-resistant *Streptococcus pneumoniae* is suspected, add vancomycin. See Infectious Diseases Society of America guidleines[176] for specifics.

[e] With chronic otitis media or sinusitis, substitute ceftazidime (150–200 mg/kg/day) or cefepime (100 mg/kg/day) as third-generation cephalosporin.

[f] Penicillin (300,000–400,000 U/kg/day) can be substituted.

[g] If no response within 1 week and organism is unknown, consider amphotericin B.

Ceftriaxone (or cefotaxime) plus metronidazole were appropriate empiric therapy for brain abscess and subdural empyema accompanying otitis media, mastoiditis, sinusitis, or CCHD before multidrug-resistant serotype 19A pneumococci (resistant to third-generation cephalosporins). Vancomycin was added to empiric regimens for coverage of resistant pneumococci and MRSA. Small numbers of patients with brain abscess have been treated successfully with alternative antibiotics, such as imipenem,[160] meropenem,[161] and ciprofloxacin,[162] but these agents have no activity against MRSA. Approximately 25% of *S. pneumoniae* 19A strains are carbapenem resistant, so carbapenem use requires confirmed susceptibility. *S. pneumoniae* 19A rarely (<3% in the

United States) is resistant to fluoroquinolones, but only anecdotal data exist for their use in intracranial abscesses. Despite the decreased prevalence of 19A strains and attendant penicillin resistance since use of 13-valent pneumococcal conjugate vaccine (PCV13), vancomycin should be included in empiric therapy for abscesses associated with otic or sinus origin and likely is needed empirically (because of a role of MRSA) in complicated sinusitis and orbital infections and (because of a role of coagulase-negative staphylococci) in focal CNS infections, such as associated with penetrating head trauma, ventriculoperitoneal shunts, or prosthetic valve endocarditis.

Vancomycin plus a third-generation cephalosporin plus an agent with anaerobic coverage is the recommended empiric regimen for CNS infections because of their polymicrobial nature. Some experts choose cefepime as the third-generation cephalosporin when *Pseudomonas* spp. is considered—that is, with chronic otitis media or sinusitis, after neurosurgery, or in immunocompromised patients.

In neonates, cefotaxime plus ampicillin is preferred because *S. pneumoniae* is rare, whereas *L. monocytogenes* and enterococci remain potential pathogens.

For brain abscess associated with α-streptococcal endocarditis on a natural valve, high-dose combination therapy recommended for endocarditis (e.g., penicillin plus aminoglycoside) is useful, although aminoglycosides in purulent collections can be relatively ineffective (low pH and low oxygen content reduce binding to ribosome). Therapy with a third-generation cephalosporin appears to be a reasonable alternative.

The rare *Nocardia* brain abscess is treated with trimethoprim-sulfamethoxazole (15 to 30 mg/kg/day divided every 6 or 8 hours). If local trimethoprim-sulfamethoxazole resistance is present or response is inadequate, a carbapenem or a third-generation cephalosporin plus amikacin or minocycline may be effective. Linezolid has been reported to be effective against multiple *Nocardia* brain abscesses.[163,164] CSF and CNS penetration of linezolid is 44% to 69% in adults.[165,166]

Prevalence of fungal species in brain abscesses parallels prevalence in other invasive fungal disease. In one review[167] including all ages, *Candida* spp. were most common (42%), followed by *Aspergillus* (29%), other molds (14%), and *Cryptococcus* (4% and mostly in adults). Endemic fungi (*Histoplasma, Blastomyces, Coccidioides*, 3%) occur mostly in defined endemic geographic areas. *Scedosporium* spp. is seen increasingly, particularly in stem cell transplant recipients.

Antifungal therapy for focal CNS infection is challenging and is based on knowledge of expected fungicidal activity against pathogens such as that confirmed, and pharmacodynamics of the drug (Table 46.7). Data from double-blind well-controlled treatment trials of CNS fungal infections are scant even for single antifungal drugs. Possible combinations of drugs are myriad given four classes of antifungal agents (polyenes, pyrimidine analogues, imidazoles, and echinocandins) and multiple class members (see pathogen-specific chapters and Chapter 293).

TABLE 46.7

Antifungal Therapy for Central Nervous System Focal Infections[177,178]

Pathogen	Therapy	Alternative Therapy
Candida spp.	Initial: AmB[a] *with or without* flucytosine[b] Step-down: fluconazole	Fluconazole
Aspergillus spp.	Voriconazole[b]	LFAmB *or* itraconazole[b] *or* posaconazole[b]
Agents of mucormycosis, e.g., *Rhizopus* spp.	L-AmB[c,d]	Other AmB or posaconazole[b,e,f]
Coccidioides immitis	Fluconazole[g]	Itraconazole[b,g] or AmB *plus* intrathecal AmB-d
Cryptococcus neoformans	Induction: AmB-d *plus* flucytosine[b] Consolidation: fluconazole, high-dose Maintenance: fluconazole	L-AmB or ABLC may substitute for AmB-d
Blastomyces dermatitidis	Initial: AmB[a] Step-down: fluconazole[e] *or* itraconazole[b,e] *or* voriconazole[b,e]	Initial therapy with an azole alone is not recommended.
Histoplasma capsulatum	Initial: L-AmB Step-down: itraconazole	AmB-d or another LFAmB may substitute for L-AmB
Scedosporium/Pseudallescheria spp.	Voriconazole[b,e,f]	Not well defined

[a] LFAmB formulations often are favored because of decreased risk for nephrotoxicity; in general, children tolerate AmB-d better than adults. L-AmB formulations attain the highest levels in the brain, whereas both L-AmB and AmB-d had the greatest antifungal efficacy in a rabbit candidiasis model that compared AmB-d, ABCD, ABLC, and L-AmB.

[b] Therapeutic drug monitoring may be beneficial.

[c] Although hyperbaric oxygen has been used as adjunct therapy, results have been controversial.

[d] Higher doses of L-AmB should be used: 5−10 mg/kg/day.

[e] Experience is limited.

[f] Susceptibility varies by species.

[g] For meningitis, some clinicians also initiate intrathecal AmB deoxycholate in addition to an azole. Patients nonresponsive to an azole would be candidates for intrathecal AmB deoxycholate with or without azole continuation.

ABCD, amphotericin B colloidal dispersion; ABLC, amphotericin B lipid complex; AmB, amphotericin B product; AmB-d, amphotericin B deoxycholate; L-AmB, liposomal amphotericin B; LFAmB, lipid formulation of amphotericin B.

Usual doses: AmB-d, 1.0–1.5 mg/kg/day; LFAmB, 3−6 mg/kg per day (varies by product and organism); fluconazole, 12 mg/kg per day; itraconazole oral suspension, 7.5−15 mg/kg/day in 3 divided doses for 3 days, then 5−10 mg/kg/day in 1 or 2 divided doses; flucytosine, 100–150 mg/kg/day in 4 divided doses; posaconazole oral suspension, age 2−12 years: 18−24 mg/kg/day in 4 divided doses, age ≥13 years: 800 mg/day in 4 divided doses (optimal pediatric dose unknown); voriconazole intravenous, age 2−11 years: 18 mg/kg/day in 2 divided doses for 1 day, then 16−18 mg/kg/day in 2 divided doses, age ≥12 years: 12 mg/kg/day in 2 divided doses for 1 day, then 8 mg/kg/day in 2 divided doses. (Dosage information courtesy of Dwight E. Yin, MD.)

Complications and Prognosis

About two thirds of patients with brain abscess recover without sequelae. Pediatric mortality fell from more than 30% in the preimaging era to 3% to 15% after use of CT.[168] Higher mortality is associated with rapid onset (<4 days), severe mental status changes at diagnosis, or rapidly progressing neurologic impairment.[148] Higher mortality also is associated with multiple abscesses[4] and with rupture of abscess into ventricles (40% mortality despite aggressive management).[169] Seizures develop in 10% to 30% of patients after treatment of brain abscess, with onset sometimes several years after treatment.[170] Frontal or temporal lobe abscess, or any large abscess, is associated with a higher incidence of seizures. Other sequelae include hemiparesis (10% to 15%), cranial nerve palsy (5% to 10%), hydrocephalus (5% to 10%), and behavioral and intellectual disorders (more serious in children <5 years of age[171]). Less common sequelae include spasticity, ataxia, optic atrophy, and visual deficits.

Outcomes for patients with subdural empyema also improved with use of CT, MRI, and improved surgical techniques[37]; mortality is less than 2%.[172] Mortality is lowest (<10%) if the patient at presentation is alert and highest (>50%) if comatose. The 5% to 10% of patients with venous sinus thrombosis accompanying subdural empyema have increased morbidity and mortality. Patients with subdural empyema have more persistent neurologic problems (15%–40%), such as seizures or hemiparesis, than patients with brain abscess.[37]

Patients with uncomplicated intracranial epidural abscess (i.e., no accompanying subdural empyema or brain abscess) have an excellent prognosis. However, delay in diagnosis can produce long-term neurologic sequelae similar to those after subdural empyema or brain abscess.

Suppurative septic sinus thrombosis with complete occlusion is associated with 25% to 35% mortality despite improved diagnostic tools and antibiotic therapy.[63] With superior sagittal sinus thrombosis, complete occlusion has the highest mortality, whereas anterior segment thrombosis commonly is associated with complete recovery.[63] Lateral sinus thrombosis has sequelae in up to 20%, such as hearing loss, decreased visual activity, brain abscess, or rarely meningitis.[111] Cavernous sinus thrombosis has sequelae in up to 33%, such as blindness, oculomotor paralysis, hemiparesis, or pituitary insufficiency.[173]

The prognosis with spinal epidural or subdural abscess is excellent if therapy begins before radicular symptoms appear. The overall mortality is less than 10%.[174] Long-term sequelae correlate with the duration of paralysis before surgery, the degree of thecal sac compression, and younger age.[76,175] Common neurologic sequelae include sphincter disturbance, spasticity, and paraparesis.

Eosinophilic Meningitis

Marian G. Michaels, Klara M. Posfay-Barbe

The finding of even a few eosinophils in human cerebrospinal fluid (CSF) raises suspicion of certain pathologic states. Helminthic infestation of the central nervous system (CNS), particularly with the rat lungworm *Angiostrongylus cantonensis,* is the most common cause of eosinophilic meningitis worldwide.[1–9] The differential diagnosis of CSF eosinophilia, however, is broad and includes infestation by other parasites, such as the raccoon ascarid *Baylisascaris procyonis*[10–19]; reaction to placement, malfunction or infection of a ventriculoperitoneal shunt[20–22]; medications[23–26]; malignancies[27,28]; hypereosinophilic syndrome[29]; and an unusual manifestation of a more common parasitic, fungal, bacterial, or viral infection of the CNS.[30–35] Table 47.1 lists the causes of eosinophilic meningitis to be considered.

TABLE 47.1

Causes of Eosinophilic Meningitis

Cause	Association With EM	Possible Transmission	Country	Comments
NEMATODES (ROUNDWORMS)	Most common causes			
Angiostrongylus cantonensis		Contact with rat lungworm; consumption	South Pacific, Africa, Australia,	Neurotropic Usually self-limited

		of snail, slug, crustacean, mollusk, crab; frogs, fish, lizards; lettuce and vegetable	Caribbean, Hawaii, US port cities	
Baylisascaris procyonis		Contact with raccoon or feces; rarely dogs, rodents, small mammals, birds	US	Neurotropic Prolonged, profound encephalitis Young children with pica are typical patients
Gnathostoma spinigerum		Contact with dog, cat; consumption of raw fish, poultry, crustaceans, amphibians	Southeast Asia, Japan, China, Mexico, Central and South America, Africa, and the Middle East	Peripheral eosinophilia common
Ascaris lumbricoides		Exposure to embryonated eggs in human feces	Worldwide	Rarely associated with EM
Trichinella spiralis		Consumption of raw or undercooked meat	Worldwide; endemic in Japan and China	Larvae usually found in skeletal muscle Rarely associated with EM
Toxocara canis, catis		Exposure to eggs in feces dogs, cats	Worldwide	Rarely associated with EM
CESTODES (TAPEWORMS)	Occasional causes			
Taenia solium		Exposure to eggs in human feces	Worldwide	Neurocysticercosis is a rare cause of EM
Echinococcus granulosus		Exposure to eggs in feces sheep; wolves, dogs, moose, reindeer	Europe; northern North America and Eurasia	Rarely infects CNS and associated with EM
OTHER PARASITES	Rare			
Toxoplasma gondii		Consumption of undercooked meat; exposure to oocyst in cat feces	Worldwide	Anecdotal report
Schistosoma japonicum		Contaminated water	Worldwide, tropical and subtropical; most cases Africa	

Paragonimus westermani		Contaminated water	Far East	Lung fluke but can invade CNS and other sites
Fasciola hepatica		Contaminated water	Worldwide; southeast Asia	
FUNGI	Occasional			
Coccidioides immitis		Exposure to aerosolized arthroconidia	Southwestern US, Mexico, South America	Low level of CSF eosinophils common; true EM also reported
Cryptococcus neoformans		Environmental exposure		Diabetes is a risk factor
BACTERIA AND VIRUSES	Case reports			
Treponema pallidum		Exposure to infected person	Worldwide	EM rarely associated with neurosyphilis
Mycobacterium tuberculosis		Exposure to infected person	Worldwide	Questionable association with direct CNS infection versus treatment
Rickettsia rickettsii		Tick bite	North, Central, and South America	Rare
Lymphocytic choriomeningitis virus		Exposure to rodents	Worldwide	Association made through serologic studies
Ventricular shunt bacterial infections				Same pathogens as in shunt infections without eosinophils
NONINFECTIOUS ETIOLOGIES	Occasional or case reports	Not applicable	All or not applicable	
Ventricular shunt complications/reaction to shunt material Bovine dural graft				No infection and improvement with removal of shunt
Systemic drugs				Reported with fluoroquinolones, nonsteroidal anti-inflammatory drugs and illicit drugs intravenously
CNS neoplasms				Reported with Hodgkin lymphoma, acute lymphoblastic leukemia, and primary CNS tumors
Hypereosinophilic syndrome				Reported in patients without other cause

Immunologic/hypersensitivity reaction				Reported with sarcoidosis or rabies vaccine

CNS, central nervous system; CSF, cerebrospinal fluid; EM, eosinophilic meningitis.

Eosinophilic meningitis is defined as (1) at least 10 eosinophils/mm^3 in CSF or (2) eosinophils making up at least 10% of the white blood cells (WBCs) in CSF, but the presence of eosinophils in the CSF should always be considered as an abnormal finding.[5] Diagnostic examination of CSF should always include Giemsa, Wright, or other stain of a cytocentrifuged specimen to delineate the exact composition of pleocytosis, as well as routine CSF examination, including Gram stain, quantitative cell count, and biochemical tests.[5]

Infectious Causes

Helminths

Angiostrongylus cantonensis

The rat lungworm, *A. cantonensis,* is the most common cause of eosinophilic meningitis worldwide. Although no cause is predominant in the United States, it is important that clinicians still consider parasitic infections in cases of eosinophilic meningitis. Travelers to endemic areas should be warned about the risks of dietary indiscretions as well. *Angiostrongylus* infestation has been the subject of several reviews.[1–4,7,9,36,37] CNS migration is characteristic of the lungworm's normal life cycle in the rat as well as in the accidental human host. Adult worms live in the rat pulmonary arteries and lay eggs in the lung. After hatching, larvae make their way through the alveolar spaces and up the trachea, from which they are swallowed and then excreted in rat feces.

Many species of slugs and snails serve as intermediate hosts, in which the larvae develop into infectious third-stage larvae. When third-stage larvae are ingested by rats, the definitive host, larvae migrate across the intestinal wall and are carried by the circulatory system to the brain. Juvenile worms have been found in the eyes, brain, and spinal cord in human infections.[38] In the CNS, larvae undergo two more moltings and mature into adult worms; the worms return to the pulmonary arteries to renew the cycle. Human infection occurs after consumption of raw snails, shrimp, or fish that have fed on infected snails. Likewise, infectious larvae can be ingested accidentally on raw vegetables, raw vegetable juice, or fomites contaminated with snail slime.[3,4,9,36,39,40] CNS tropism is retained in human infection; however, the life cycle is disrupted, and generally, the disease is self-limited, with larvae dying in the CNS.

Human infection by *A. cantonensis* probably is more widespread than believed and has been found in Asia, notably in Thailand, Malaysia, and China; the South Pacific, including Taiwan, Hawaii, American Samoa, New Guinea, Indonesia, and Australia; India, Egypt, Brazil, and the Caribbean.[1–4,8,41–43] Worms can migrate on ships within their natural hosts (the rat) to distant countries, including mainland United States.[40] The first published, nonimported case in the US was a child from New Orleans who reported eating a raw snail "on a dare."[43] The child had meningitis that abated with supportive care.

In adults, symptoms classically begin 2 to 35 days after infection, with acute onset of headaches.[1–4] Other common complaints are nausea and vomiting, weakness, paresthesias or hyperesthesias, pruritus, somnolence, and cranial nerve palsies, especially optic nerve and cranial nerves VII and VIII.[1–4,40,44] About 20% of patients also have a stiff neck.[38] Fever, if present, usually is of low grade. Hearing loss has been reported, as has retinal detachment or hemorrhage.[18,45] Periorbital cellulitis can be associated. Most patients recover completely, with symptoms beginning to abate within several weeks of the initial neurologic manifestations. Headaches and paresthesias can be more persistent.[3,44] Neurologic symptoms may be due to mechanical damage caused by worm migration in the brain as well as the neurotoxicity of eosinophil-derived basic proteins.

Infected children may not complain of headache. Clinical manifestations in younger patients can be more insidious, with upper respiratory symptoms, cough, and fever preceding mental status changes, seizures, or focal neurologic abnormalities.[2,6,39] Psychiatric changes also have been reported.[46] One series of 16 young adults consuming raw infected great African *Achatina fulica* snails in American Samoa was notable for the absence of headache as a major complaint.[47] All of the patients experienced severe radiculomyeloencephalitis; one died. Unlike other intermediate hosts or contaminated vegetables, *A. fulica* snails can harbor thousands of parasites, possibly accounting for the more fulminant course in patients who acquire parasites from consuming these snails. Other reported fatalities or sequelae are observed primarily in young children, who are at risk for acquiring a relatively higher infectious load.[2,39,48]

CSF examination reveals pleocytosis typically between 150 and 2000 WBCs/mm^3.[1,2,47] Peak eosinophilia occurs between 2 and 4 weeks of illness, with CSF eosinophils representing a median of 49% of the total WBCs (range, 15%–97%).[1–4,6,39,48] The CSF protein value often is elevated, and the glucose value is normal or mildly decreased.[1,2] Peripheral blood eosinophilia is common but does not correlate with the extent of CNS eosinophilia.[1,2,4] Coincident infections with other parasites may contribute to peripheral eosinophilia.

A diagnosis of eosinophilic meningitis usually is made on the basis of clinical presentation in patients who are from or are traveling from an area enzootic for *A. cantonensis* and have a consistent dietary history. The history of eating raw seafood can be absent in young children who have a propensity for pica.[6,39,48] On occasion, worms are found in the CSF, especially if a large-bore cannula is used for removal of CSF or if CSF is aspirated rather than allowed to flow by gravity.[2] Enzyme immunosorbent assays to detect antibody in serum or CSF have been developed and are available in enzootic areas and can be facilitated by contact with the Centers for Disease Control and Prevention, Disease Surveillance Division of Parasitic Infections (770-488-7775).[3,4]

Baylisascaris procyonis

The ascarid parasite of the raccoon, *Baylisascaris procyonis,* is found in 20% to 90% of both rural and urban raccoons in the US.[11,49–51] Evidence of raccoon latrines near human habitation[50] increases the concern for this emerging infection, which has been highlighted in several reviews.[15,52] Like *A. cantonensis,* this ascarid migrates through the CNS during its normal life cycle and is neurotropic in humans.[10,11,15,52] The ascarid causes little disease in the raccoon, but ingestion of eggs by aberrant hosts, such as foxes, rabbits, birds, and humans, can result in migration of larvae, causing severe CNS damage. Experimental disease in nonhuman primates consists of eosinophilic meningitis, neurologic deterioration, coma, and death (discussed in references 11, 15, and 52). Despite the high prevalence of this parasite in raccoons, *B. procyonis* is rarely documented in humans. In the US, just more than a dozen clinical cases have been reported, most commonly in young children, resulting in eosinophilic meningoencephalitis with dramatic eosinophilic CSF pleocytosis, severe neurologic devastation, and death in 6 patients.[10,11,15,52–55] Ocular larva migrans and visceral larva migrans also can occur.[15,56] Exposure to raccoon droppings near nesting sites is the expected mode of acquisition. Behavior related to substance abuse has been identified as a possible risk factor.[57] Because clinician awareness of this parasite is limited, and diagnosis is not straightforward, it is possible that the disease is more widespread and that less severe symptoms remain undiagnosed.[58] Asymptomatic infection has been suspected by finding a low level of seropositivity in otherwise healthy children (reviewed in references 15 and 52). As improved serodiagnostic assays become more readily available, the true incidence and clinical array will become more apparent. Currently serologic testing of serum and CSF is only available from the Department for Veterinary Pathobiology at Purdue University, West Lafayette, IN (765-494-7558).

Gnathostoma spinigerum

The nematode of dogs and cats, *Gnathostoma spinigerum,* is found commonly in Thailand and other parts of Southeast Asia, but its prevalence is increasing in Mexico and Central and South America.[44] *Gnathostoma* can cause visceral larva migrans when it infects humans who consume raw or undercooked fish, frogs, pigs, snakes, fowl, eels, or poultry containing third-stage larvae or, rarely, have direct larval penetration of the skin.[22,36,44] Gnathostomiasis typically presents as cutaneous, visceral, or CNS forms. Gnathostomiasis most often is characterized by migratory subcutaneous nodules, but larvae can wander to organs and cause local symptoms[59] or enter the CNS through the nerve root, causing a myeloencephalitis.[18,59,60] Patients can manifest disease over a period of a year, with intermittent intense nerve root pain followed by paralysis or sudden deterioration in mental status.[18,59] The CSF shows a striking eosinophilia but often also can have many red blood cells or xanthochromia. Frequently, *G. spinigerum* infection is associated with concurrent peripheral blood eosinophilia, which is pronounced.[36,59,60] Infection can be severe and results in death more often than infection with *A. cantonensis*.[1,5] Diagnosis is challenging; blood eosinophilia may be lacking, or head computed tomography can show nodular lesions, area of hemorrhage, or hydrocephalus.[44]

Other Infectious Causes

Other parasites can invade the CNS, including *Taenia solium, Toxocara canis, Taenia cati, Toxoplasma gondii, Paragonimus westermani, Fasciola hepatica, Trichinella spiralis, Ascaris lumbricoides, Echinococcus granulosus, Schistosoma japonicum,* and *Onchocerca volvulus.* Associated CSF eosinophilic pleocytosis characteristically is mild.[3,5,13,35,36,61]

Bacterial meningitis occasionally can be associated with mild degrees of CSF eosinophilic pleocytosis. The first descriptions of eosinophilic meningitis were in patients with neurosyphilis.[5] Other implicated agents are *Mycobacterium tuberculosis*, group B *Streptococcus*, and *Rickettsia rickettsii*.[32,33,62,63]

A retrospective review of 27 adults in the southwestern US with *Coccidioides immitis* meningitis noted eosinophils in the CSF of 70% of patients; 30% of instances met the definition of eosinophilic meningitis.[34] Other fungal infections of the CNS, such as those due to *Histoplasma capsulatum* or *Cryptococcus neoformans,* and *Aspergillus* species are occasionally associated with CSF eosinophilia.[64,65] Rarely, viral infections of the CNS (lymphocytic choriomeningitis virus, coxsackieviruses B3 and B4, measles virus, echovirus 6, and varicella-zoster virus) have been associated with eosinophilic pleocytosis of CSF.[30,31,63] In some of these cases, diagnosis was suggested by results of serologic testing or by isolation of the virus from sites other than the CNS.[30,31]

Noninfectious Causes

Review of series of children with complications of ventriculoperitoneal shunts have shown varying rates of eosinophilic pleocytosis associated with bacterial infection,[22,63] intraventricular administration of antibiotics,[24] or antibiotic-impregnated ventriculostomy catheters,[25] or without any risk factor other than the shunt itself.[20] In one series evaluating 558 shunt insertions, 36 (6.5%) were found to have more than 8% eosinophils in the CSF.[20] Affected children characteristically had experienced excessive numbers of shunt revisions and shunt infections. Another study demonstrated activation of eosinophils in CSF related to shunt obstruction.[21] This study found that 6.4% of 404 children with ventriculoperitoneal shunts had transient CSF eosinophilia.[21] However, in most of these children, the eosinophilia value was no more than 3%, or eosinophils were present before placement of the shunt. Vinchon and associates[22] reported finding eosinophilic meningitis associated with 27 of 81 presumed bacterial shunt infections; CSF culture results were positive in 63% of cases, and the microbes found did not differ from the types of organisms found in patients with noneosinophilic shunt infections. Persistent eosinophilic pleocytosis, failure to isolate infectious agents in many cases, and an association with eventual extrusion of subcutaneous tubing in some populations suggest that hypersensitivity to shunt material occasionally occurs. Replacement of the shunt with one of a different material sometimes is undertaken and sometimes is curative. One report associated the use of a minocycline- and rifampin-impregnated ventricular drain in a child with a shunt malfunction and the development of eosinophilic pleocytosis; eosinophilia resolved coincident with corticosteroid administration and removal of the tubing.[25]

Several other noninfectious possibilities are included in the differential diagnosis of eosinophilic meningitis. Systemic drug administration has been associated on occasion with aseptic meningitis, and, more rarely, fluoroquinolone and nonsteroidal anti-inflammatory agents have been associated with eosinophilic meningitis.[23,36] In addition, CNS involvement with Hodgkin primary lymphoma[27] or acute lymphoblastic leukemia[28] has caused eosinophilic meningitis. Other primary CNS tumors (as well as aseptic meningitis after resection of tumors) can be associated with mild eosinophilic pleocytosis.[63] Patients with sarcoidosis and hypereosinophilia syndrome have been reported to have accompanying eosinophilic meningitis.[29,63] Eosinophilic meningitis also has been described in two intravenous drug users who were negative for human immunodeficiency virus or other identifiable infections.[66] The authors postulate that this might represent an eosinophilic response to systemically injected drug adulterants that were used as cut substances for street drugs.

Diagnosis and Treatment

Careful attention to the clinical setting (i.e., occurrence, history of exposure or travel) and findings on physical examination almost invariably narrow possible causes of eosinophilic meningitis to one or two categories. Careful examination of large amounts of CSF for parasites and malignant cells and culture of CSF for fungus can yield a diagnosis.

Examination of stool for ova and parasites often is unrewarding because most human neurotropic parasites do not complete the life cycle in humans. However, (1) parasitic infestations often occur concurrently and (2) on occasion, *A. lumbricoides, S. japonicum, T. solium,* and *F. hepatica* have been associated with eosinophilic meningitis. Therefore stool evaluation is justified. Serologic tests of the CSF and serum for *C. neoformans* (CSF antigen test), *A. cantonensis,* or *B. procyonis,* when epidemiologically indicated, are appropriate. However, for angiostrongyliasis, the sensitivity and specificity of serologic assays vary greatly, rarely exceed 80%, and may present cross-reactivity with other microorganisms, such as *Gnasthostoma* spp.[38,44] Reliable antigen-specific immunoassays are still needed. CSF often is cloudy, with increased opening pressure and protein concentration but normal glucose concentration. Neuroimaging can be of benefit and can guide biopsy of the meninges or brain if other tests do not confirm a diagnosis. Approximately half of the patients have abnormal magnetic resonance imaging results, with leptomeningeal enhancement and lesions in the brain parenchyma or hydrocephalus.[44,67]

The treatment and prognosis of parasitic and infectious causes of eosinophilic meningitis or meningoencephalitis depend on the cause, underlying conditions, and extent of involvement at time of diagnosis. Recommendations for specific therapies can be found in chapters addressing individual pathogens.

No systematic study of treatment with antiparasitic agents has been undertaken for *A. cantonensis,* and treatment is primarily supportive. A multicenter study prospectively evaluated patients between 2 and 65 years of age with eosinophilic meningitis; 19% of patients were younger than 20 years. Treatment was not dictated by the study; however, no difference was noted in course or outcome among patients who received 5 days of corticosteroid therapy, antibiotics, or analgesics alone.[1] Uncontrolled studies have reported the use of corticosteroids to be beneficial.[68,69] A randomized controlled trial in adults in Thailand showed no benefit of prednisolone plus albendazole compared with prednisolone alone.[25,68] Another group reported in a placebo-controlled trial that albendazole decreased the duration of headache in adult patients. The revised Cochrane review showed that only a single randomized controlled trial demonstrated that corticosteroids decrease headache, making the evidence of usefulness of moderate quality.[70] In mice, anti-CCR3 monoclonal antibodies decreased significantly the eosinophil infiltration of the brain and may offer new possibilities for future treatment in human. Observations that clinical improvement occurs after (repeated) lumbar puncture or is temporally related to use of corticosteroid and mannitol suggest that some symptoms may be a consequence of the inflammatory response, raised intracranial pressure, or both.[1,2,29]

Children with severe eosinophilic meningitis due to *Baylisascaris* have not been shown to benefit from treatment; however, experimentally infected mice were protected from neurologic disease if treated with albendazole or diethylcarbazine before larvae entering the brain (reviewed in reference 15). In some cases, antipsychotic drugs have been used as well in specific cases.[46] Because of the potential for severe, even fatal, outcome, particularly in young children, some experts recommend treatment of children exposed to raccoon excrement with albendazole to prevent disease.[15,50,52]

Educating the public about potential dangers from exposures to raccoons and their feces is the most important component of prevention. Raccoons have adapted readily to human habitats and are attracted to areas with sources of water and food. Therefore their presence should be discouraged by cleaning up areas and ensuring that food is not left out unwittingly. Parents of toddlers in particular should be mindful of potentially contaminated play areas, encourage good handwashing after playing outside, and discourage pica.

Urinary Tract Infections, Renal Abscess, and Other Complex Renal Infections

Michael Davenport, Linda M. Dairiki Shortliffe

Infections of the genitourinary tract in children remain a significant health concern, with more than 1.1 million US physician visits annually.[1] Of all infectious agents, bacteria are the most common cause of urinary tract infection (UTI). In infants, UTI is a common cause of fever and may result in renal parenchymal damage and functional loss. As such, rapid diagnosis, proper treatment, and prevention of recurrent UTI are key to reducing renal damage.

Etiologic Agents

The most common bacteria that cause UTI are gram-negative Enterobacteriaceae, primarily *Escherichia coli* and then *Klebsiella*, *Proteus*, *Pseudomonas,* and *Enterobacter* spp. Some serotypes of *E.*

coli, including uropathogenic *E. coli* (UPEC) and extraintestinal *E. coli,* contain specific cell wall O-antigens that facilitate infection.[2–4] Gram-positive organisms other than *Enterococcus* spp. are less common causes of UTI, and isolates such as *Staphylococcus saprophyticus* account for only 15% of pediatric UTIs. *Staphylococcus aureus,* including methicillin-resistant strains, rarely cause symptomatic UTI, and isolation in the urine should suggest primary infection elsewhere. Infections caused by *Pseudomonas* spp. should be considered in children who have been hospitalized recently, had prior episodes of UTI, or had prior antibiotic treatment.[5]

Viral cystitis can occur in immunocompromised hosts. In children with a history of bone marrow transplantation, BK virus can cause a severe hemorrhagic cystitis that improves only with immunologic recovery.[6,7] Levofloxacin has failed to show prophylactic benefit for managing BK virus infection in patients after transplantation, despite in vitro activity of the drug.[8]

Epidemiology

UTI accounts for 2.4% to 2.8% of pediatric physician visits, 51 hospitalizations per 100,000 children, and 174 hospitalizations per 100,000 infants each year.[1] Girls are hospitalized 2.5 times more often than boys.[9,10] During the first year of life boys have more UTIs than girls.[4,11] For uncircumcised boys the risk for UTI is 10 times greater than for circumcised boys during the first year.[12]

Definitions

Using routine culture techniques, normal urine shows no bacterial growth (i.e., <100 colony-forming units [CFUs]/mL for catheter-obtained specimen and <1000 CFUs/mL for clean-catch specimen). There is, however, controversy about whether urinary tract colonization (“benign bacteriuria”) occurs. UTI is diagnosed when an appropriately collected urinary specimen shows growth of defined density for UTI diagnosis.

Because the anatomic level of UTI is difficult to determine without specific invasive techniques or excessive imaging, *UTI*—in this chapter and unless otherwise specified—refers to urinary tract bacteriuria with accompanying symptoms and signs—a spectrum from cystitis with lower tract bladder symptoms to pyelonephritis with systemic and abdominal symptoms.

Pathogenesis

UTI begins with bacterial adherence to host epithelial cells along a fecal-perineal-urethral route, with potential retrograde ascent of bacteria along the urinary tract.[13] Aspects of bacterial virulence and patient risk factors influence this course but do not predict pyelonephritis, renal scarring, or parenchymal and functional loss. Of the 3% of girls and 1% of boys who have UTI prepubertally, about 17% will have infection-related renal scarring.[4] Of children with scarring, 10% to 20% may develop renal-related hypertension. A child only rarely progresses to end-stage renal disease requiring transplantation because of UTI.

Bacteria must overcome urethral defenses to cause UTI. These defenses include (1) urethral washout, (2) epithelial shedding, and (3) paraurethral glandular secretion.[14] Also, host defenses such as toll-like receptors triggered by bacterial lipopolysaccharide and urinary Tamm-Horsfall protein may adhere to uropathogenic *E. coli* and assist urethral washout.[15]

Two important markers of *E. coli* virulence are mannose-resistant hemagglutination and P blood group–specific adhesion (P-fimbriae or P-pili).[16–18] Attachment between the uroepithelial cell and bacteria through type 1 pili and fimbriae initiates a molecular interaction that allows for bacterial uptake into the umbrella cells on the bladder surface.[19] Intracellular bacteria then transform into biofilms that allow for microbial adaption and systemic infection, antimicrobial resistance through plasmid exchange, endotoxin production, and increased resistance to host systems.[20] When in the bladder, retrograde ascent from the bladder to kidney is affected by host immunity, impaired ureteral peristalsis, vesicoureteral reflux (VUR), and organism-specific uropathogenicity.

Risk Factors for Bacteruria and Renal

Damage

Age.

The prevalence of UTI in both males and females younger than 1 year of age is higher than at any other time during childhood. This may be due to a number of factors including density of periurethral colonization, lack of breastfeeding, immature immune status, and, in boys, circumcision status.

Race and Ethnicity.

Epidemiologic studies show racial variance in the prevalence and complications, with Asian, Hispanic/Latino, and white children having higher rates of UTI than black children.[2,21] Black children also have less VUR and renal scarring compared with other races.[1,21,22]

Genetic Predisposition.

Genetic factors that may predispose to UTI include blood group phenotypes, such as P1 blood group, ABO, Lewis secretor phenotypes, host genetic polymorphisms of adhesion molecules (ICAM-1), transforming growth factor-β, toll-like receptor, and vascular endothelial growth factor.[23–25] Being younger than 15 years of age at first UTI (odd ratio, 3.9) and having a history of maternal UTI (odds ratio, 2.3) are risk factors for recurrent UTI in girls.[26] Predisposition for pyelonephritis correlates with decreased expression of interleukin-8 receptors (CXCR1) on peripheral neutrophils regardless of VUR status.[24,27]

Colonization.

The incidence of UTI is higher during the first few months of life than at any subsequent time in a healthy childhood. During this time the periurethral area of healthy infants is extensively colonized with aerobic bacteria, such as *E. coli*, enterococci, and staphylococci.[28] Periurethral colonization decreases to low density during the first year of life, and after the age of 5 years, colonization is associated with recurrent UTI. For the first 6 months of life, uncircumcised infant boys have greater periurethral colonization than circumcised boys[12,29–32]; during this time, uncircumcised boys have more UTIs than circumcised boys.

Immune Status.

After birth, levels of serum immunoglobulin G (IgG) and IgA fall to a nadir at 3 months and periurethral colonization high.[33,34] During this period breastfeeding may protect against UTI and other infections because immunoglobulins, particularly secretory IgA, and oligosaccharides in maternal milk may inhibit adherence of *E. coli* to uroepithelium.[35,36]

Sexual Activity.

Sexual activity is a risk factor for UTI. The upsurge of UTI in adolescents may signal the onset of sexual activity in teenagers[37]; the prevalence of *Chlamydia* is 13% to 26% and *Neisseria gonorrhoeae* is 2% to 10% in this population. Male and female teenagers who have dysuria, urinary frequency, or urgency should be evaluated for both UTI and sexually transmitted infections.

Obesity.

Obesity can be associated with chronic indolent inflammation that increases susceptibility to infections. Compared with lean children, obese children have an 80% increased risk for developing cystitis and an almost 100% increased risk for developing pyelonephritis.[38] These findings mirror those in adults.

Genitourinary Anatomic and Functional Abnormalities.

Studied after a first UTI, 40% to 56% of children have imaging abnormalities,[39,40] the most common abnormalities being hydronephrosis found in 34% and VUR in 30%.

The presence of VUR does not correlate with increased susceptibility to UTI[4] but does correlate with an increased likelihood of developing pyelonephritis after bacteriuria. VUR is a congenital abnormality that results from immature or inadequate muscular support at the ureteral orifice, facilitating retrograde urinary flow from the bladder into the ureter and pelvicaliceal system. Thus, infected retrograde urinary flow can lead to pyelonephritis. Children with high-grade reflux appear to be at greater risk for renal damage compared with children with low-grade reflux.[41,42] Uropathogenic virulence may be more likely to predict development of pyelonephritis and subsequent nephropathy than the degree of reflux.[43]

Whether related to neuropathic bladder dysfunction, ineffective spontaneous bladder emptying,[44] or more subtle increased postvoid residual bladder urine with or without VUR,[45] dysfunctional voiding is associated with increased UTIs.

Identifying anatomic or functional urinary tract abnormalities in the setting of UTI is important because correction can reduce the risk for persistent or recurrent infection. A nidus of bacterial persistence, such as struvite stones, papillary necrosis, or sites of poor antimicrobial penetration (poorly functioning duplicated segments) may be removed, or VUR causing recurrent pyelonephritis can be repaired.

Clinical Manifestations

UTI should be considered in infants and young children who have fever or other signs of infection. Children may present with flank pain accompanied by fever, chills, nausea, or vomiting. Other symptoms can include dysuria, frequency, incontinence, and urgency. Although parents may mention the presence of malodorous urine, this has not been correlated with UTI.[46]

Adolescents with lower urinary tract symptoms should be evaluated for both UTI and sexually transmitted infection. Because UTI is relatively uncommon in adolescent males, they should be evaluated for structural abnormalities, such as previously undiagnosed obstruction, ectopic collecting systems, or voiding dysfunction. Older children are more likely to localize tenderness on palpation and may report pain in the suprapubic and flank region. A palpable flank mass can be caused by hydronephrosis, pyonephrosis, or xanthogranulomatous pyelonephritis.

Laboratory Findings

Urinary Specimens

Obtaining an uncontaminated urine specimen to diagnose infection accurately can be difficult, particularly in young children. Of the various methods for urine collection, suprapubic aspirate is the most reliable because it bypasses potential urethral and periurethral contamination. Although the presence of bacteria in a suprapubic aspirate is diagnostic of a UTI, practitioners avoid this technique because of its perceived invasive nature.

In most cases, urethral catheterization can be performed in a sterile fashion, providing adequate sampling for urinalysis and culture; risks for catheterization include urethral trauma and the introduction of bacteria into the bladder. Voided urinary specimens generally are reliable in circumcised boys, older girls who can retract labial tissue while urinating, or older uncircumcised boys who can retract the foreskin reliably to reduce contamination by resident flora. Bagged urinary specimens are the least reliable method of collecting urine and are useful only when the culture result is negative.[47–49] Even with extensive cleansing of the surrounding skin, the bagged urine specimen typically contains perineal and rectal flora.

Urinalysis

Findings of urinalysis that support a diagnosis of UTI include (1) pyuria, defined as more than 5 white blood cells (WBCs) per high-power field (HPF) in a centrifuged specimen; (2) any bacteria visualized under high power in an unstained centrifuged urinary sediment (×40); (3) presence of urinary leukocyte esterase; and (4) positive test for urinary nitrite. Urinary leukocyte esterase is a byproduct of the degradation of WBCs in the urine. The urinary nitrite test measures dietary nitrates reduced to nitrates by gram-negative Enterobacteriaceae. Gram-positive bacteria, yeasts, and organism such as *Pseudomonas* spp. do not reduce dietary nitrates. Assuming a urine specimen has been collected appropriately, the combination of a result of positive leukocyte esterase and nitrite tests and microscopic visualization of bacteria approaches positive predictive value of nearly 100% for UTI and allows presumptive treatment.[49,50] When all components (or leukocyte esterase and nitrite tests) are negative, the negative predictive value approaches 100%.

In children younger than 2 years, the sensitivity of routine urinalysis for UTI is only about 80%.[51,52] In a multicenter analyses of infants younger than 3 months with bacteremic UTI (identical organism in the blood and urine), investigators found that the sensitivity of leukocyte esterase and pyuria (>3 WBCs/HPF 96%) each exceeded 95%.[53]

Urine Culture

Quantitative urine culture is the gold standard for the diagnosis of UTI. Traditionally, a UTI has been defined as growth of 100,000 CFUs/mL from a voided urine sample.[54] Guidelines from 2011 suggest that the presence of pyuria plus bacterial growth of 50,000 CFUs/mL or more is sufficient for UTI diagnosis.[55] Under some circumstances (e.g., suprapubic aspiration) the presence of less than 10,000 CFUs/mL can be consistent with infection.

Serum Tests

Although urinary culture is the standard for diagnosing UTI, other tests to predict the severity of infection have been examined. For example, elevated erythrocyte sedimentation rate and C-reactive protein have been associated with severity of bacterial infection.[56] Procalcitonin is a hormonally inactive precursor of calcitonin and is elevated in sepsis. Two meta-analyses correlated elevated procalcitonin with both pyelonephritis and high-grade VUR.[57–59]

Urinary Tract Infection Imaging Evaluation

Radiologic imaging often is used in the evaluation of children with febrile UTI. Imaging studies can demonstrate the extent and location of an acute UTI, detect renal damage from infection, identify underlying genitourinary abnormalities that may predispose to future infection, and follow the development of the renal/urinary system over time. Issues of timing of imaging after UTI, optimal modalities, and importance and significance of diagnosing VUR are controversial.

Prior recommendations for performance of renal and bladder ultrasonography and voiding cystourethrogram (VCUG) resulted in high rates of normal findings in children with upper and lower urinary tract infections, respectively. These findings have resulted in attempts to limit UTI imaging, in particular VCUG, given high cost, exposure to ionizing radiation, and invasive catheterization. Current guidelines limit UTI imaging to be more efficient and less invasive UTI evaluation (Royal College Physicians, National Institute for Health and Care Excellence [NICE], American Academy of Pediatrics [AAP], and others).

NICE published guidelines in 2007 that recommend the selective use of ultrasonography for children with atypical UTI, infants younger than 6 months of age, and children with recurrent UTI.[60] Dimercaptosuccinic acid scintigraphy (DMSA) is recommended 4 to 6 months after an atypical UTI in children younger than 3 years and for all children with recurrent UTI. VCUG is not recommended as part of evaluation after a typical first UTI.

Guidelines published by the AAP in 2011 recommend the performance of VCUG in children who have abnormal ultrasonography with hydronephrosis, a second febrile UTI, renal scarring, or atypical or complicating factors that might be associated with high-grade VUR.[55]

Multiple investigators are examining the health implications of these latest recommendations from NICE and AAP. There is lack of agreement on the relevance of diagnosing all grades of VUR, especially when considering the patient discomfort, costs, and radiation exposure resulting from VCUG.

Retrospective analyses using these guidelines observe that most “missed” abnormalities are VUR.[61–64] When kidney-bladder ultrasonography is used in the evaluation of children with UTI, “missed” abnormalities appear to be both uncommon and clinically insignificant.[65–68] Although most analyses concluded that following newer guidelines decreases use of imaging, one study concluded that the 2007 NICE guidelines increase the numbers of DMSA studies performed.[69]

Several groups have proposed further refinements to the guidelines based on these data. Kidney Health Australia guidelines recommend the use of renal ultrasonography in children with UTI who are bacteremic, younger than 3 months, or infected with atypical organisms (e.g., *Staphylococcus* and *Pseudomonas* spp.) or have poor clinical response after 48 hours, renal impairment, significant electrolyte imbalance, abdominal mass, or poor urinary stream. Other groups recommend using high serum procalcitonin concentrations and the presence of dilated ureters as imaging criteria to enhance the detection of high-grade VUR.[68,70] The European Association of Urology/European Society of Pediatric Urology recommends the use of ultrasonography after the first UTI and more widespread use of VCUG in children with UTI.[71]

In all cases when appropriate UTI management is not followed by expected improvement, more extensive imaging such as magnetic resonance urography or DMSA scan should be considered. Current controversies and concerns emphasize a need for improved risk analyses and diagnostic imaging stratification for children with UTI.

Other Imaging Findings

In addition to structural anomalies, such as congenital obstruction or VUR, findings such as hydronephrosis or perinephric stranding may be seen with acute pyelonephritis. Renal ultrasonography may show areas of focal hypoechogenicity or hyperechogenicity that represent localized, severe, and nonliquefactive infection of the renal lobules seen in focal pyelonephritis, or lobar nephronia.[72,73] Previously diagnosed hydronephrosis or pelviectasis may reveal transient increase on imaging during acute UTI, secondary to increased collecting system pressure caused by infection.[74,75] Renal damage also can be seen on functional studies such as DMSA scans and magnetic resonance urography.

Management

Antimicrobial Treatment

Children younger than 3 months of age can have rapid progression of infection, and as many as 30% are bacteremic.[76–78] As a result, these children are usually hospitalized for treatment with intravenous antibiotics. In this age group, gram-negative bacteria are the most common cause of UTI. Infection also can be caused by *Listeria monocytogenes* and *Enterococcus* species, which can be acquired perinatally and postnatally, respectively.[79] Considering etiology, treatment with ampicillin and gentamicin typically is recommended in this age group.

Children older than 1 month who do not have major genitourinary abnormalities and can take fluids and oral medications can be treated effectively with either a complete course of oral antibiotics, or 2 to 4 days of parenteral therapy followed by oral therapy for a total duration of 10 to 14 days.[80] Studies comparing the effectiveness of oral and parenteral therapy typically excluded children with impaired renal function, severe urinary tract abnormalities including VUR grades 3 to 5, immune compromise, signs of shock, and recurrent UTI. In these patient groups, more intensive therapy should be considered.

Oral medications that have been studied and found to be effective include cefixime, ceftibuten, and amoxicillin-clavulanic acid.[80] Resistance of more than 30% of *E. coli* to amoxicillin-clavulanate makes it a poor choice for empiric therapy.

Presumed lower urinary tract infections in children can be treated effectively with relatively short courses of an oral antibiotic. Whereas 10 days of therapy are more likely to eradicate bacteriuria than 1 day of therapy, no differences in cure rates have been observed in simple cases in older children for those treated for 2 to 4 days compared with 7 to 10 days.[81]

Antibiotic Resistance and Selection of Antimicrobial Agents

For children with UTI requiring parental antibiotic treatment, third-generation cephalosporins, such as ceftriaxone, provide broad-spectrum coverage and effectively treat most Enterobacteriaceae but are not active against enterococci.[71]

Aminoglycosides provide excellent coverage against gram-negative pathogens.[82] Once-daily dosing of aminoglycosides is safe and effective and facilitates outpatient treatment. To limit bacterial resistance and alterations of the microbiome, one should consider the drug with the narrowest spectrum and shortest course that will be efficacious.

Nitrofurantoin is active against most uropathogens. Although it has low serum concentration, it is concentrated in the urine and therefore works well for the treatment of cystitis, except for those with poor renal concentrating ability. Because of low serum concentrations, it is a poor choice for the treatment of pyelonephritis or systemic infection.[83] Despite many years of use, bacterial resistance to nitrofurantoin is low.

Fluoroquinolones are commonly used for the treatment of UTI in adults, but experience in children is limited. Ciprofloxacin and levofloxacin are approved for the treatment of children with complicated UTI and pyelonephritis, are orally bioavailable, and have activity against *Pseudomonas aeruginosa*.[5] Oxytetracycline is an alternative agent that can be considered for the oral therapy of UTI caused by *Pseudomonas* spp.[84]

Many uropathogens now are resistant to commonly used antibiotics, including ampicillin and trimethoprim-sulfamethoxazole, and, in some institutions, they are also resistant to quinolones.[78,85–87] Risk factors for resistance include recent hospitalization, recent receipt of antibiotics, urethral catheter, and a complicating urologic condition, such as urologic anatomic malformation and renal segments with poor function.[88,89]

Ambulatory medical settings may provide rates of bacterial resistance based on practitioner antibiotic usage; patients from ambulatory urology clinics have been found to have higher rates of *E. coli* resistance compared with other general and hospital medical settings within the same institution.[86] These factors portend potential antimicrobial resistance and should prompt consideration of alternative drugs.[90]

Antibiotic Prophylaxis

The daily administration of antibiotics to prevent recurrent UTI in children would be useful if future morbidities and renal damage could be avoided without undue risk.[91,92] A Cochrane systematic review demonstrated only small decreases in recurrent symptomatic UTI.[93]

Two large placebo-controlled trials, PREVENT (Prevention of Recurrent Urinary Tract Infection in Children with Vesicoureteric Reflux and Normal Renal Tracts)[94] and RIVUR (Randomized Intervention for Children with Vesicoureteral Reflux),[95] concluded that long-term low-dose trimethoprim-sulfamethoxazole (TMP-SMX) decreased recurrent symptomatic UTIs. PREVENT enrolled children from birth to 18 years who had at least one symptomatic UTI with or without VUR. Based on their results, the PREVENT authors concluded that antibiotic prophylaxis for children who had a single symptomatic UTI was not recommended.

RIVUR included children from 2 to 71 months of age with grades 1 to 4 VUR. Children received randomized double-blind therapy (TMP-SMX versus placebo) and were followed for 2 years. Investigators found recurrent UTI in 39 of 302 children receiving antimicrobial prophylaxis and 72 of 305 children on placebo (relative risk, 0.55). Prophylaxis was more effective in those with index febrile UTI and bladder and bowel dysfunction. There was no significant difference in renal scarring outcome.

Antibiotics used for UTI prophylaxis should attain high urinary concentrations, to maximally inhibit uropathogens, and low serum concentrations, to minimally affect other flora. Additionally, the agent should be inexpensive, easily administered, and well tolerated. Parental compliance with prophylaxis has been estimated to be 40% to 69%.[96] Prophylaxis decreases the frequency of recurrent UTI but the effect on eventual renal function is not clear.

Complications and Sequelae

Children at increased risk for renal scarring include those with infections associated with high temperatures (>39° C), those who have abnormal ultrasonography, and those with infections caused by organisms other than *E. coli*.[97]

Recurrent UTIs in children who have renal scars is more likely to be associated with the development of hypertension and progressive renal dysfunction. Data from a large cohort of children with more than 11 mean years of follow-up noted that 15% had unilateral renal parenchymal defects, primarily occurring among those with reflux. Blood pressure and renal function were normal in all children.[42] However, these findings differ from an older investigation by Smellie and associates, who examined long-term consequences of UTI and found hypertension and abnormal renal function in 8%; these latter children had frequent *recurrent* UTI.[98] This study also emphasized that those with normal kidneys at baseline rarely developed new scars. Population-based data from developed countries support that childhood UTI rarely is associated with long-term renal function deterioration.[99]

Craig and others reported that end-stage renal failure attributable to UTI is low (about 2%–3%) in developed countries. In contrast, reflux nephropathy is a significant cause of end-stage renal disease (about 7%–17%) in under resourced countries.[100] There are no data associating childhood or recurrent UTI with renal failure in children with normal urologic anatomy and normal kidneys on imaging.[101]

Focal Bacterial Nephritis (Acute Lobar Nephronia) and Perinephric Abscess

Severe pyelonephritis may evolve into an inflammatory mass without drainable pus known as *acute focal bacterial nephritis* (AFBN). This is an intermediate stage between pyelonephritis and intrarenal abscess. Similar to renal abscess, AFBN results from hematogenous or ascending infection and is more commonly observed in patients with genitourinary malformations such as VUR. AFBN can be distinguished from renal abscess by imaging that shows a lobar or wedge-shaped distribution of hypodense or hyperdense lesions without a clear abscess wall.[102,103]

Although differentiating between AFBN and abscess was important when open renal drainage was the main treatment for abscesses, this differentiation is difficult, and current management is based on other factors. Improvements in imaging of the genitourinary tract and use of broad-spectrum antimicrobial agents have changed the evaluation and natural history of perinephric and renal abscesses.[104] The high mortality rates associated with perinephric abscess associated with diagnostic delays now are rare because of widespread availability of computed tomography (CT) and magnetic resonance imaging (MRI).

Although childhood perinephric and renal abscesses were common 50 years ago,[105] they now are infrequent in developed countries. Renal abscesses arise from either hematogenous seeding from extragenital sites of infection or renal extension of ascending urinary infections. Although hematogenous seeding of *S. aureus* from skin and soft tissue sites was a common cause of past renal abscesses in children and adults, any resulting renal abscess is uncommon when skin infections are treated promptly.

Currently, gram-negative organisms (e.g., *E. coli*) from retrograde extension of ascending bacteriuria are the most common cause of renal and perirenal abscesses.[106–109] Anaerobic bacteria can cause perinephric or renal abscesses in association with previous abdominal surgery, renal transplantation, malignancy, and oral or dental infection[110]; other fastidious organisms,, such as *Ureaplasma* spp., have been reported to cause abscesses in immunocompromised patients.[111]

Children with renal and perirenal abscesses have symptoms of severe pyelonephritis, including fever, flank pain, leukocytosis, and occasionally sepsis. Because abscesses have a fluid component, perinephric collections usually appear lucent (hypoechoic) on ultrasonography, and guided diagnostic aspiration for culture usually carries minimal morbidity. Although most children with renal abscess have a urinary culture growing gram-negative organisms (commonly *E. coli*), *S. aureus* can be causative. A negative urinary culture does not eliminate the possibility of renal abscess.[112]

When UTI does not respond to appropriate management, advanced imaging is required to evaluate for a more complicated infection. CT and MRI can assess abscess extent and can show perirenal fluid or gas, renal distortion, and involvement of the retroperitoneum.[113–115]

Retrospective reviews conclude that modern imaging assessment may permit the management of most renal abscesses with antibiotics alone.[116,117] When there is poor response or obstructive uropathy, however, percutaneous or surgical drainage combined with appropriate antibiotic therapy may be required.[116,118]

Pyonephrosis

Pyonephrosis is characterized by accumulation of purulent debris and sediment in the renal pelvis and urinary collecting system. Children with pyonephrosis have symptoms similar to acute pyelonephritis but have additional structural obstructive hydronephrosis. This situation usually implies bacterial infection and obstruction (pus under elevated pressure), so rapid diagnosis and treatment are essential to avoid extravasation, sepsis, and parenchymal loss. Most partially obstructed kidneys with pyonephrosis are either nonfunctioning or poorly functioning.

Renal ultrasonography may show shifting fluid-debris levels with changes in the patient's position, persistent echoes from the lower collecting system, air in the collecting system, or weak echoes secondary to pus in a dilated poorly transonic renal collecting system.[119] When pyonephrosis and obstruction are present together, antimicrobial agent penetration and efficacy can be impaired because of edema and poor blood flow into the area. The treatment for pyonephrosis is combination of optimal antimicrobial therapy and prompt drainage to deflate the infected pelvis by either retrograde catheterization or nephrostomy placement.

Xanthogranulomatous Pyelonephritis

Under certain circumstances, chronic bacterial pyelonephritis and obstruction are associated with a distinct severe inflammatory process known as *xanthogranulomatous pyelonephritis* (XGP). Although XGP occurs in only about 1% of cases and is now diagnosed more frequently with imaging,[120,121] the diagnosis is important because XGP can be confused with childhood renal tumors (Wilms tumor, multilocular cystic nephroma, congenital mesoblastic nephroma, malignant rhabdoid, and clear cell sarcoma). Although the cause is unknown, the process usually is associated with both infection and obstruction.

XGP is less common in children than adults. Symptoms include flank pain, fever, chills, and chronic bacteriuria. Vague symptoms of malaise, malnutrition, weight loss, and failure to thrive often are present. Lower tract irritative symptoms are uncommon. Most patients with XGP have had symptoms for longer than a month.[121,122]

The most common infecting organisms are *Proteus* spp. and *E. coli*. Urine contains white blood cells and protein; anemia, reflecting the chronic nature of the disease, is common. The process usually is unilateral and can involve pericalyceal tissue alone (focal) or the kidney diffusely (diffuse), with extension into the perinephric fat, and even the retroperitoneum with encasement of the great vessels.[120,123]

In children, XGP often affects those younger than 8 years and is of the focal rather than diffuse form (17%–25% of cases). Boys are affected more frequently, and contralateral renal hypertrophy can be present.[122,124] Although obstructive calculi occur in both children and adults, obstruction may involve congenital genitourinary abnormalities in children.

Radiologic findings include renal calculi in 38% to 70% of patients; nonfunctioning renal segments in 27% to 80%, and a mass in as many as 62%.[120,125] Ultrasonography can show an enlarged kidney with hypoechoic areas that represent areas of necrosis and pus-filled calyces. CT with contrast shows areas of low attenuation that do not enhance and may show extension of the mass into the perinephric fat. Grossly the kidney shows yellow-white nodules and evidence of pyonephrosis. The histologic diagnostic feature is the xanthoma cell—a foamy lipid-laden histiocyte that can simulate the renal carcinoma cell. These xanthoma cells also can appear in other tissues and conditions of chronic inflammation and obstruction such as obstructive pneumonia.

Complex Urinary Tract Infections: Imaging Evaluation

Computed Tomography and Magnetic Resonance Imaging

More complicated renal abnormalities and UTIs with a spectrum of pyonephrosis, abscess, calculi, and infection require more extensive three-dimensional imaging. Although seldom used to evaluate acute renal inflammatory processes unless unusual or complicating anatomic configurations are seen on ultrasonography, CT or MRI can reveal detailed and sensitive signs of acute renal inflammation. These modalities often are able to differentiate and distinguish between inflammatory, neoplastic, and other renal masses seen using other imaging modalities.

Acute inflammatory changes of the kidney can be described as (1) unilateral or bilateral, (2) focal or diffuse, (3) with or without focal swelling, and (4) with or without renal enlargement. Other features that can be seen during the various phases are cortical hypoattenuation, wedge defects, poor corticomedullary differentiation during the nephrogram phases, and linear bands of alternating hyperattenuation and hypoattenuation parallel to the tubules and collecting ducts, creating a striated effect during the excretory phase. Scans delayed 3 hours or longer may help to differentiate renal abscess from hypofunctioning parenchyma in severe pyelonephritis.[126] It is notable that acute focal pyelonephritis (or lobar nephronia) has been misinterpreted as renal abscess by CT because of an appearance of acutely decreased central lobar perfusion, and at times guided needle aspiration may be needed to clarify the clinical situation.

Risks of Ionizing Radiation and Responsible Imaging

There is evidence for a linear increase in excess lifetime solid cancer and leukemia risk for radiation exposure from 1 to 150 mSv and highest for those exposed as children.[127,128] Concern specifically relates to childhood radiation exposure because (1) childhood radiation has a longer time span during which effects may become manifest, (2) developing cells have greater potential for developing direct damage from radiation exposure, and (3) medical and diagnostic procedure radiation appropriate for adults is often unadjusted for children, causing disproportionately high radiation exposure.

CT scan with and without contrast in a child using pediatric settings will give an effective radiation dose of 6 to 10 mSv, almost 3.5 years of equivalent background radiation,[129] and the estimated lifetime cancer mortality rate from an abdominal pediatric CT in a 1-year old is 0.18%.[130]

Radiation exposure risks to young developing infants and children must be considered carefully as practitioners consider individualized evaluation of UTI. Radiation risk to children may be limited in two ways: (1) decreased exposure through technologic imaging advances and (2) practitioner decision analysis in which imaging studies with risk for ionizing radiation exposure are selected only when information obtained likely would alter management. Although there are few data indicating that MRI is better than CT, there are data indicating that, except when renal calculi are suspected, MRI is as good as CT and confers advantages in pediatric urinary tract imaging.[114,115,131]

Special Considerations

Urinary Tract Infection and Circumcision

The 2012 recommendations of the AAP state that "health benefits of newborn male circumcision out-weigh the risks, and the benefits of newborn male circumcision justify access to this procedure for those families who choose it."[132] The AAP literature review concludes that circumcision may reduce risk for UTI and sexually transmitted infections such as HIV, herpes simplex virus type 2, human papillomavirus, and invasive penile cancer. The AAP recommends that that clinicians give educational material to parents and that parents determine what is in the best interest of their child.

Covert or Asymptomatic Bacteriuria

Covert and asymptomatic bacteriuria usually are defined as genitourinary tract colonization by bacteria that do not activate a local or systemic response—therefore causing few symptoms. Bacteriuria ("UTI") is found on incidental testing or screening. Whether bacteriuria truly is asymptomatic sometimes is not clear because children may exhibit nocturnal or diurnal enuresis, urinary urgency, and squatting. At least 20% of children with asymptomatic bacteriuria have a history of UTI, and only 50% have normal imaging of the genitourinary tract; this led some experts previously to consider bacteruria on par with symptomatic UTI.[10,133]

Most children with asymptomatic bacteriuria clear the bacteria without intervention.[134,135] A study from Sweden found that the median time to clearance was 2 months in girls and 1.5 months in boys.[136]

Although evidence for and against treatment of covert or asymptomatic bacteriuria is sparse and inconclusive, reviews and Cochrane analysis of available studies do not demonstrate that antibiotic treatment confers benefit.[137,138] Children with asymptomatic bacteriuria and a known normal urinary tract need no follow-up UTI screening or imaging. Antibiotic treatment should be avoided, unless surgery involving the urinary tract is planned or the patient becomes pregnant.[71,139]

Recurrent Urinary Tract Infection and a

Normal Genitourinary System

In evaluating children for recurrent infection, it is important to differentiate between bacterial reinfection and bacterial persistence. The former involves reinfection with the same or new organism after the initial UTI was cleared[4]; the latter indicates that the original infection was never properly cleared because an infected nidus persists (e.g., struvite infection stone, bacterial prostatitis, urethral diverticulum).[140]

About 20% of those who develop a UTI have a recurrent infection.[141] For a girl who has a UTI, the risk for developing another UTI within 1 year is directly proportional to the number of previous infections, regardless of the severity of prior infections. In a child with frequently recurrent UTI, defined as two or more infections in a 6-month period, prophylactic antibiotics may provide benefit.[4,142] After the antibiotics are stopped, however, the child typically reverts to repeated UTIs; sometimes recurrent UTI can be related to bowel and bladder dysfunction, and management of voiding habits and constipation may decrease UTI frequency.[143]

Healthcare-Associated Urinary Tract Infection

The urinary tract is the most common site of nosocomial infection, and prevention of catheter associated urinary tract infections is a critical measure in reducing healthcare-associated morbidity and improving healthcare quality.[21,144] There is no evidence to support the use of antimicrobial prophylaxis before routine urethral catheterization.

Positive culture of a bladder urinary specimen from an indwelling urethral catheter in place for longer than 3 to 4 days should be considered as a sign of infection.[145,146] Because the catheter surface becomes covered with a biofilm, persistent bacteriuria is inevitable with long-term catheter drainage, and these hospital-acquired UTIs often are resistant to routine antimicrobial treatment.[147] There is no evidence that cultures of urethral catheter tips correlate with routine urinary cultures; thus there is no need to culture the catheter tip.[148] Infectious complications associated with urethral catheterization include acute epididymo-orchitis, pyelonephritis, periurethral abscess, and infectious calculi such as struvite stones. Replacement or obstruction of the urinary catheter can cause transient or acute bacteremia or sepsis, especially if bacteriuria is present. To decrease these complications, culture and treatment of bacteriuria before catheter removal or presumptive treatment at the time of removal is prudent.

Cardiovascular Abnormalities or Prophylaxis for Genitourinary Manipulation

Most often, children who have indwelling catheters, nephrostomy tubes, other foreign bodies within the urinary tract, or open drainage systems such as ileal conduits or catheterizable stomas are at high risk for bacteriuria; presumptive or definitive treatment should be given before urinary tract procedures.

In the past, antimicrobial prophylaxis was recommended before catheter placement or urinary tract manipulation for children with cardiac abnormalities; however, the American Heart Association no longer recommends antibiotic prophylaxis "solely to prevent infective endocarditis" for genitourinary tract procedures.[149] Antimicrobial prophylaxis against enterococcal infective endocarditis is appropriate in those with heart defects at highest risk for infective endocarditis (prosthetic cardiac valves, previous infective endocarditis, congenital heart disease—unrepaired cyanotic heart disease, for 6 months after heart defect repair with prosthetic materials, heart defects with residual defects near the prosthesis, and cardiac transplantation).[149,150] For patients who undergo elective urinary tract surgery, UTI should be treated before the procedure. For those in whom the procedure is not elective, antimicrobial prophylaxis with a drug active against enterococcus should be considered.

A survey of US pediatric cardiologists noted that many continue to recommend preprocedure antimicrobial prophylaxis "even when not recommended to do so per the 2007 AHA guidelines."[151] Using a decision-based cost-effectiveness analysis of retrospective data, others calculate that infective endocarditis prophylaxis before urinary catheterization of children (0–24 months of age) evaluated in emergency departments for fever is not cost-effective.[152] A child with an indwelling urinary collecting device should be considered to have bacteriuria.

Fungal Urinary Tract Infection

Fungal UTI has become an increasingly prevalent healthcare-associated infection, particularly in patients who recently received antimicrobial agents or recently were catheterized.[153,154] Predisposing factors include recent antimicrobial therapy, prematurity, intravenous or umbilical artery catheterization, parenteral nutrition, and immunocompromised state.[155] Differentiating between fungal contamination, colonization, and infection is important but often is challenging.[156]

A carefully collected second specimen frequently can verify contamination. Symptoms and signs may be inadequate to distinguish between colonization and infection. Although children can have bladder irritative symptoms as found with bacterial UTI, young children and those with other impairments may be unable to appreciate or communicate symptoms. In these children, further imaging to examine for fungal upper tract infection or obstructing fungus balls may be needed.

Prophylactic administration of oral nystatin or fluconazole in very low birth weight infants (<1000−1500 g) is useful in the prevention of fungal colonization and invasive infection.[157,158] *Candida albicans* is the most commonly isolated species and is responsible for half of all infections. *Candida glabrata* is the next most common isolate. It is important to recognize this because *C. glabrata* frequently is resistant to fluconazole.[154]

Renal ultrasonography can be useful in evaluating the extent of fungal infection. Fungal bezoars can form in the renal pelvis, causing obstruction and potentially anuria in infants with bilateral involvement.[155,159–161] Urinary alkalization or oral and intravenous antifungal chemotherapy may "dissolve" some of these fungal balls. In small infants, fungal mass can cause obstruction; percutaneous or open removal of the bezoars may be required. Therapy can then proceed with local irrigation and systemic antifungal treatment to clear the infection.

The decision to treat asymptomatic funguria in the setting of an indwelling urethral catheter is controversial; the progression to disseminated candidemia is uncommon.[154] Therefore treatment is recommended when cultures repeatedly yield more than 10,000–15,000 CFUs/mL.[162] Treatment measures include (1) stopping all unnecessary antimicrobial agents, (2) changing or removing the indwelling catheter, (3) urinary alkalization, and for persistent colonization (4) irrigation of the bladder with amphotericin B, administration of oral fluconazole, or both. Recurrence of fungal colonization is common.[163,164]

Key Points

Diagnosis and Management of Urinary Tract Infections

Epidemiology

- Girls are hospitalized 2.5 times more often than boys.
- In the first year of life, boys have more UTIs than girls; in uncircumcised boys, risk for UTI is 10 times more than in circumcised.
- Risk factors: age, race/ethnicity, genetics, periurethral colonization, immune status, sexual activity, obesity, genitourinary abnormalities, voiding dysfunction, constipation

Imaging Evaluation

- Perform ultrasonography with selective voiding cystourethrography
- Consider using imaging evaluations that do not use ionizing radiation

Treatment and Management

- Children without major genitourinary abnormalities older than 1 month who are otherwise healthy may be treated with oral antibiotics for 10–14 days.
- Bacterial antimicrobial resistance is affected by regional and local factors and antibiotic exposures.

- Low-dose antimicrobial prophylaxis decreases recurrent UTI but increases antimicrobial resistance.

- Focus should be to identify UTI risk factors that may be modified to prevent future infections.

UTI, urinary tract infection.

Sexually Transmitted Infection Syndromes

Margaret J. Blythe

Recent surveys of high school students indicate that almost one half of them are sexually active, including almost two thirds of senior students. Reported percentages for males and females do not vary.[1] Sexually transmitted infections (STIs) are common and have the potential for significant health and economic consequences for youth in the United States. The US Centers for Disease Control and Prevention (CDC) estimate 19.7 million new sexually transmitted infections occurred in 2013, with one half occurring among people between the ages of 15 and 24 years and an almost equal distribution between boys (51%) and girls (49%).[2]

Confidentiality is extremely important for adolescents and young adults seeking reproductive healthcare. Providers must feel comfortable taking a comprehensive history and discussing behaviors that place teens and young adults at risk for STIs. Confidential testing, appropriate treatment, and counseling on partner notification are important parts of care.[3]

Genitourinary Syndromes

STI manifestations in adolescents and young adults can be divided into six clinical syndromes: (1) discharge and dysuria, (2) anal discharge and proctitis, (3) genital ulcer and lymphadenopathy, (4) pelvic or scrotal pain, (5) pharyngeal infection, and (6) dermatologic syndromes.

Discharge and Dysuria Syndrome

Presentation

Male urethritis is characterized by acute or chronic inflammation defined microscopically by visualization of leukocytes. Signs of urethritis may be seen with or without symptoms and include mucoid or purulent urethral discharge, dysuria, urethral pruritus, and meatal erythema. Female urethritis due to STIs may be asymptomatic but manifests clinically as dysuria, which is suspected when white blood cells (WBCs) are documented in urine with a negative urine culture (i.e., sterile pyuria). Urethral syndrome in women (i.e., dysuria, frequency, and sterile pyuria) can accompany cervicovaginal infection due to meatal irritation or urethral infection. Clinical features of vaginal discharge include altered color, odor, quantity, and accompanying pruritus, but none is a reliable predictor of the cause of genital discharge and dysuria. Vaginal discharge and dysuria may be accompanied by abnormal vaginal bleeding, dyspareunia, and mild pelvic pain. Sterile pyuria and vaginal discharge suggest cervicitis, which may be accompanied by a normal-appearing cervix on examination with a purulent or mucopurulent discharge at the cervical os or sustained endocervical bleeding referred to as *cervical friability*.[3]

Etiologic Agents

Genital discharge or dysuria syndrome usually is caused by one of four primary infectious agents: *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, *Trichomonas vaginalis*, or *Mycoplasma genitalium* (Table 49.1). Most published studies include populations from sexually transmitted disease clinics where Gram stain is used for diagnostic evaluations of male patients (Table 49.2). Demographics, region of the country, sexual practices, and diagnostic testing may suggest or confirm the cause. For example, urethritis can be acquired by fellatio, and it sometimes results from transmitted chlamydial or gonorrheal infections or pathogens found in the pharynx (e.g., adenovirus).[4,5]

TABLE 49.1

Sexually Transmitted Infection Syndromes in Adolescents and Young Adults

STI Syndrome	Primary Organisms	Other Causal Organisms
GENITOURINARY SYNDROMES		
Discharge and dysuria	*Chlamydia trachomatis* *Neisseria gonorrhoeae* *Trichomonas vaginalis* *Mycoplasma genitalium*	*Ureaplasma urealyticum* *Mycoplasma hominis* Herpes simplex virus 1, 2
Proctitis, proctocolitis, and enteritis	*Chlamydia trachomatis* *Neisseria gonorrhoeae* *Treponema pallidum* Herpes simplex virus 1, 2	*Campylobacter* species *Entamoeba histolytica* *Giardia lamblia* *Salmonella* species *Shigella* species
Genital ulcer and lymphadenopathy	Herpes simplex virus 1, 2 *Treponema pallidum*	*Calymmatobacterium granulomatis* *Haemophilus ducreyi* *Chlamydia trachomatis* lymphogranuloma venereum
Pelvic pain (e.g., pelvic inflammatory disease)	*Chlamydia trachomatis* *Neisseria gonorrhoeae* *Mycoplasma genitalium*	*Mycoplasma hominis* Mixed aerobic and anaerobic bacteria
Scrotal pain (e.g., epididymitis)	*Chlamydia trachomatis* *Neisseria gonorrhoeae*	*Mycoplasma genitalium* *Ureaplasma urealyticum*
PHARYNGEAL SYNDROMES		
Infections of pharyngeal mucosa	*Neisseria gonorrhoeae* Herpes simplex virus 1, 2	*Treponema pallidum* Human papillomaviruses
DERMATOLOGIC SYNDROMES		
Genital warts	Human papillomaviruses	—
Molluscum contagiosum	Molluscum contagiosum virus	—
Rash, alopecia	*Treponema pallidum*	—
Arthritis and dermatitis syndrome	*Neisseria gonorrhoeae* *Chlamydia trachomatis*	—
Jaundice, hepatitis	Hepatitis A, B, C viruses	—
Scabies	*Sarcoptes scabiei*	—
Pubic lice	*Phthirus pubis*	—

TABLE 49.2

Tests Used to Determine the Cause of Sexually Transmitted Infection Syndromes in Adolescents and Young Adults

STI Syndrome	Office Tests Available	Preferred Laboratory Tests
GENITOURINARY SYNDROMES		
Discharge and dysuria	Females: microscopic wet prep vaginal secretions, pH paper, whiff test, KOH; LET; rapid tests for GC, CT, TV, BV, and	Females, males: NAATs for GC, CT, and TV; HIV test

	HIV; UPT Males: Gram stain smear of urethral discharge looking for ≥5 WBCs per oil immersion field and intracellular gram-negative diplococci; LET; microscopic examination of first-void spun urine sediment with ≥10 WBCs per high-power field; rapid tests for GC, CT, and HIV	
Proctitis, proctocolitis, and enteritis	Females, males: Gram stain smear of anorectal exudate; rapid test for HIV Females: UPT	NAATs for GC and CT; see HSV and syphilis under genital ulcer; cultures for other gram-negative pathogens and ameba; HIV test
Genital ulcer and lymphadenopathy	Females, males: darkfield examination for syphilis; rapid test for HIV Females: UPT	Cultures for HSV-1 and HSV-2 or PCR for HSV; serology for type-specific glycoprotein G to discern HSV-1 or HSV-2 RPR or VDRL and confirmatory tests for syphilis if positive or treponemal EIA or CIA chemiluminescence immunoassays and confirmatory nontreponemal test (RPR or VDRL) if positive NAATs for *C. trachomatis;* PCR genotyping or serology for LGV (complement fixation or microimmunofluorescence) Gram stain and culture for chancroid; staining for Donovan bodies on tissue biopsy; HIV test
Pelvic pain (e.g., pelvic inflammatory disease)	Microscopic wet prep vaginal secretions, pH paper, whiff test, KOH; LET; rapid tests for GC, CT, TV, BV, and HIV; UPT	NAATs for GC, CT, and TV; HIV test
Scrotal pain (e.g., epididymitis)	Gram stain smear of urethral discharge looking for ≥5 WBCs per oil immersion field and intracellular gram-negative diplococci; LET; microscopic examination of first-void spun urine sediment with ≥10 WBCs per high-power field on first-void urine; rapid tests for GC, CT, and HIV	NAATs for GC and CT; HIV test
PHARYNGEAL SYNDROMES		
Infections of pharyngeal mucosa	Rapid strep test	NAATs or culture for GC and CT; culture or PCR for HSV-1 and HSV-2, serology for type-specific glycoprotein G to discern HSV-1 and HSV-2; RPR or VDRL and confirmatory tests if positive; HIV test
DERMATOLOGIC SYNDROMES		
Genital warts	Characteristic lesions	
Molluscum contagiosum	Characteristic lesions	Wright or Giemsa staining for intracytoplasmic inclusions
Rash, alopecia	—	RPR or VDRL and confirmatory tests if positive

Arthritis, dermatitis	Males: Gram stain smear urethral discharge looking for ≥5 WBCs per oil immersion field and intracellular gram-negative diplococci; LET Females: Microscopic wet prep vaginal secretions for WBCs; LET; rapid tests for GC, CT; and UPT	Females, males: NAATs or culture for GC and CT from rectum or pharynx Females: NAATs of vaginal swab Males: NAATs of first-void urine
Jaundice, hepatitis	—	Appropriate laboratory tests for hepatitis
Scabies	Microscopic examination of skin and hair	—
Pubic lice	Identification of eggs, nymphs, and lice with naked eye or microscopy	—

BV, Bacterial vaginosis; CIA, chemiluminescence immunoassay; CT, *Chlamydia trachomatis*; EIA, enzyme immunoassay; GC, *Neisseria gonorrhoeae*; HIV, human immunodeficiency virus; HSV-1, herpes simplex type 1; HSV-2, herpes simplex type 2; KOH, potassium hydroxide; LET, leukocyte esterase test of urine; LGV, lymphogranuloma venereum; NAATs, nucleic acid amplification tests; RPR, rapid plasma reagin; STI, Sexually Transmitted Infection; TV, *Trichomonas vaginalis*; UPT, urine pregnancy test, VDRL, Venereal Disease Research Laboratory; WBCs, white blood cells.

Where US testing is available for male patents, *M. genitalium* has been reported as the cause of 15% to 25% of symptomatic nongonoccocal urethritis (NGU) cases. Presenting symptoms and physical findings for the different pathogens are similar. For women, the role *M. genitalium* plays in urethral syndrome compared with cervicitis is less clear.[6,7]

Management

Point-of-care office tests should be performed to determine the cause and guide therapy to prevent complications, reinfection, and transmission (see Table 49.2).[3,8,9] Nucleic acid amplification tests (NAATs) are preferred for the detection of *C. trachomatis* and *N. gonorrhoeae*; optimal specimens are vaginal swabs from women and first-catch urine from men.[3,9] If an infection is identified, appropriate treatment should be given and sex partners referred for evaluation and treatment.

Empiric treatment for chlamydial and gonorrheal infections is recommended for symptomatic men at high risk for infection or who are unlikely to return for follow-up.

The prevalence of *T. vaginalis* is 2% to 3% among adolescents, with higher prevalences documented in selected populations.[10–12] The most common method of detection in female patients is microscopic evaluation of a wet preparation of vaginal secretions, which has a sensitivity in at-risk populations of 50% to 65%.[12,13] Although commercial reference laboratories have validated NAAT for *T. vaginalis*, none of the assays is cleared by the US Food and Drug Administration (FDA).[9,14] In-office tests are FDA cleared to detect *T. vaginalis* in vaginal secretions but are not approved for use on urine samples.[15,16] There is no FDA-approved test available for *M. genitalium*.[6]

Anal Discharge, Proctitis, Proctocolitis, and Enteritis Syndrome

Presentation

Sexually transmitted gastrointestinal syndromes include proctitis, proctocolitis, and enteritis. Different organisms should be considered based on sexual behaviors, history of symptoms, exposure to similar illnesses, and physical examination findings (see Table 49.1). Predominantly associated with receptive anal intercourse, proctitis is inflammation of the rectum resulting in rectal discharge, anorectal pain, and tenesmus. Rectal infections without a history of anal sex can occur in females but not males.[3]

Etiologic Agents

The most common sexually transmitted pathogens reported include *N. gonorrhoeae, C. trachomatis* (including serovars L1, L2, and L3), *Treponema pallidum*, and herpes simplex virus (HSV) (see Table 49.1).[17,18] In one large, multicenter, case-control study, symptomatic proctitis due to *C. trachomatis* lymphogranuloma venereum (LGV) serovars was more likely associated with tenesmus, constipation, anal discharge, and weight loss compared with those with other causes.[19]

Depending on the pathogen, proctocolitis extending up to 12 cm above the anus can be acquired through receptive anal intercourse or by oral-anal contact. Symptoms are similar to proctitis but include diarrhea or abdominal cramps. LGV proctocolitis can lead to chronic colorectal fistulas and strictures with secondary bacterial infections.[3] Other opportunistic agents as cytomegalovirus (CMV) can be involved in immunosuppressed patients infected with human immunodeficiency virus (HIV). Enteritis usually results in diarrhea and abdominal cramping without signs of proctitis or proctocolitis and occurs among persons whose sexual practices include oral-anal contact. In otherwise healthy persons, *Giardia lamblia* is most frequently implicated, whereas those with HIV may have a variety of pathogens that may not be sexually transmitted.[3]

Management

Evaluation should include an anoscopic examination with th anorectal exudate evaluated by Gram stain for WBCs and intracellular gram-negative diplococci. All persons should be evaluated for gonococcus, chlamydia, syphilis, and HSV infection (see Table 49.2). If the chlamydia test result is positive for a rectal swab, testing for LGV should be performed. NAAT is more sensitive than culture and is the preferred method for detection of *N. gonorrhoeae* and *C. trachomatis* anorectal infections.[9]

Empiric treatment should be initiated based on clinical presentation. It should then be adjusted according to diagnostic test results.

Genital Ulcer and Lymphadenopathy Syndrome

Presentation and Etiologic Agents

In the United States, most young, sexually active patients with genital, anal, or perianal ulcers have genital herpes or syphilis. Less common infectious causes of genital, anal, or perianal ulcers include chancroid, LGV, and donovanosis (see Table 49.1).

Herpes Simplex Virus.

Approximately 776,000 new cases of genital herpes are diagnosed annually, with 45% of cases occurring in patients 15 to 24 years of age.[2] Genital herpes may be caused by type 1 or 2 HSV(HSV-1 or HSV-2). Based on data from the National Health and Nutrition Examination Survey (NHANES), HSV-1–positive serologic results for children between the ages of 14 and 19 years decreased from 39% during the 1999–2004 period to 30% during 2005–2010 period. HSV-2–positive serologic results decreased from 1.6% to 1.2% over the same timeframe. The declines in childhood acquisition of HSV-1 along with the increase in oral-genital sexual behaviors that occur during adolescence make teenagers more vulnerable to acquisition of genital HSV-1 infections.[20]

Initial symptoms can be limited to pain, burning, or pruritus in the area where lesions eventually appear. Development of single vesicle or small groups of vesicles typically follows within a few hours. Vesicles often are quite painful, and they progress to ulcers over a period of a few days. Tender, usually bilateral, inguinal lymphadenopathy can appear at this time.

The length of viral shedding and time required to heal depend on whether the infection is primary (i.e., seronegative for HSV-1 and HSV-2 antibodies), nonprimary (i.e., HSV-2 infection with pre-existing HSV-1 antibodies), or recurrent (i.e., HSV genital outbreak with the same HSV type). For primary infections, viral shedding continues for 10 to 12 days, and healing requires up to 3 weeks. For recurrent infections, shedding occurs for up to 4 days, with healing in 5 to 7 days.[21]

Syphilis.

Primary syphilis is an important cause of genital ulcer and lymphadenopathy syndrome, although it is relatively uncommon among US adolescents. If untreated, infection facilitates the transmission of HIV acquisition. During 2013 to 2014, the rates of primary and secondary syphilis increased 14.4% for men (from 10.3 to 11.8 cases per 100,000 men) and 22.7% for women (from 0.9 to 1.2 cases per 100,000 women).[22]

The classic primary syphilis lesion is a single, deep, indurated, painless ulcer associated with unilateral, nonfluctuant, ipsilateral inguinal lymphadenopathy. Multiple chancres occur in approximately 25% of cases. These lesions occur about 3 weeks (range, 10 to 90 days) after sexual contact with an infected person. Untreated infections heal spontaneously without treatment in 1 to 6 weeks. Lesions can occur almost anywhere in the genital and rectal area. Perianal and rectal chancres usually are the result of rectal intercourse for men.

Other Causes.

Other causes of genital ulcer disease are rare in the United States, with sporadic outbreaks of LGV occurring primarily among HIV-infected men who have sex with men (MSM). LGV is caused by *C. trachomatis* serovars L1 through L3 after an incubation period of 3 to 12 days.

Most infections begin as an asymptomatic, self-limited ulcer, papule, or erosion at the site of infection and can be associated with nonspecific urethritis. Lesions typically progress to tender, unilateral femoral or inguinal lymphadenopathy. By the time patients seek care, the lesions have often disappeared. Most reported infections in MSM were found in the anorectal canal and not the urogenital area.[23]

A rare cause of genital ulcer and lymphadenopathy syndrome in the United States is *Haemophilus ducreyi* (i.e., chancroid), a gram-negative anaerobic bacillus. Since 2001, the number of US cases has fluctuated, with only 6 cases reported in 2014.[22] The incubation period usually is 4 to 7 days, and there are no prodromal symptoms. Lesions are tender papules surrounded by erythema that become pustular, erode, and then form painful ulcerations over 14 to 48 hours, progressing to painful, suppurative lymphadenopathy.

Granuloma inguinale (i.e., donovanosis), caused by *Klebsiella* (*Calymmatobacterium*) *granulomatis*, can be considered as a possible case of genital ulcerative disease if the infection was acquired in a developing country or by sexual contact with someone traveling from a developing country. Lesions typically are painless, highly vascular, and beefy red, and they gradually progress to ulcerations without regional lymphadenopathy. Subcutaneous nodules also can be associated with infection.[3]

Management

Most persons infected with HSV-2 have not received a diagnosis.[22,24] Subclinical shedding of HSV-2 occurs whether the disease is symptomatic or not, and it accounts for disease transmission.[25] All patients who have genital, anal, or perianal ulcers should be evaluated for genital herpes and syphilis (see Table 49.2). In areas where chancroid is prevalent, a test for *H. ducreyi* should be performed.

Genital and lymph node specimens (i.e., lesion swab or bubo aspirate) also can be tested for *C. trachomatis* by NAAT. Chlamydial NAATs are not FDA cleared for testing these specimens, but some laboratories have validated the assays.[9] Additional serologic tests are used to differentiate LGV from non-LGV *C. trachomatis*. In the absence of specific testing, patients with a clinical syndrome consistent with LGV, including proctocolitis or genital ulcer disease with lymphadenopathy, should be presumptively treated for LGV.[3]

Pelvic or Scrotal Pain Syndrome

Presentation and Etiologic Agents

Pelvic or scrotal pain often is associated with an STI in adolescents and young adults. Pelvic pain is common in female patients with pelvic inflammatory disease (PID). PID comprises a spectrum of inflammatory disorders of the upper female genital tract, including any combination of endometritis, salpingitis, tubo-ovarian abscess, and pelvic peritonitis. PID symptoms can be mild or severe; mild cases often are unrecognized.

The clinical diagnosis of PID is imprecise and relies on historical and clinical indicators. Due to the significance of disease sequelae, empiric therapy for PID should be initiated in sexually active teenagers and young adults experiencing pelvic or lower abdominal pain without an identifiable cause who meet the minimal criteria of cervical motion tenderness, uterine tenderness, or adnexal tenderness on physical examination.[3] Specificity can be increased with evidence of associated lower genital tract infection and inflammation. Additional supportive criteria include a temperature greater than 38.3°C, an elevated erythrocyte sedimentation rate or C-reactive protein level, or laboratory documentation of *N. gonorrhoeae* or *C. trachomatis* infection. Microorganisms that comprise the vaginal flora and *M. genitalium* also have been associated with PID.[7] Empiric therapy should be initiated based on appropriate clinical symptoms even if further supporting evidence is not available.

Scrotal pain in young men at risk for STIs most often represents epididymitis. Presentation usually is insidious, with onset of unilateral scrotal pain, tenderness, and swelling in the affected area. Torsion of the testicle first must be excluded with an imaging evaluation. Patients often have a history of dysuria and urethral discharge. Fever or bilateral involvement is uncommon. Alleviation of pain with gentle manual elevation of the affected side (i.e., Prehn sign) supports the diagnosis.[3]

Management

Infection is indicated by a positive leukocyte esterase result on a first void urine specimen from males or females or at least 10 WBCs per high-power field on a first-void urine sediment from males. A urine pregnancy test, urine dipstick for nitrites, and culture always should be performed for female patient because ectopic pregnancy, urinary tract infection, and pyelonephritis can cause pelvic pain.[3] All women who have acute PID should be screened for HIV infection and tested for *N. gonorrhoeae* and *C. trachomatis* using NAATs, and presumptive treatment should be initiated.

Among young men, gonorrhea and chlamydia are the most commonly identified causes, and NAATs used for male urine are preferred (see Table 49.2). Presumptive treatment for both organisms is indicated. The role of *M. genitalium* in PID and epididymitis is not known, and testing for the organism is not currently available.[3,7]

Pharyngeal Syndromes

Gonococcal and chlamydial infections occur on mucosal surfaces lined with columnar epithelium, including the pharynx, and most infections are asymptomatic. Routine screening of clinics serving MSM detected prevalence rates 1% to 2% for chlamydial infections and 3% to 7% for gonorrhea.[26]

The clinical significance of asymptomatic pharyngeal chlamydia infection is unknown except for sexual transmission.[7] Gonococcal pharyngeal infection may be asymptomatic or manifest as mild infection with pharyngeal erythema. Undetected gonococcal infection of the pharynx can result in sexual transmission to a partner, may rarely result in disseminated gonorrhea infection, and may also contribute to development of gonococcal antimicrobial resistance.[7,26]

HSV-1 and HSV-2 can infect the pharynx and manifest as fever, malaise, myalgia, headache, tender anterior cervical lymphadenopathy, and sore throat with mild ulcerations and diffuse erythema. Oral syphilis can cause painless chancres on the lips, buccal mucosa, tonsils, and pharynx; lesions on the tonsils and pharynx may be painful. Oral and laryngeal papillomas due to human papillomavirus (HPV) can appear after oral-genital contact. Nononcogenic, low-risk HPV types 6 and 11 are the cause of recurrent respiratory papillomatosis, whereas persistent infection with oncogenic HPV type 16 is the strongest risk factor for development of HPV-associated oropharyngeal cancer.[3,27]

Dermatologic Syndromes

HPV subtypes 6 and 11 are responsible for 90% of genital warts.[27] Oncogenic subtypes 16, 18, 31, 33, and 35 can be associated with genital warts but usually are coinfections with types 6 and 11.[3] Common squamous epithelial sites of warts are the glans, prepuce, urethral meatus, shaft of the penis, and perianal area for young men. In young women, warts are found on almost any area of the vulva, perianal area, vagina, and cervix. HPV types 6 and 11 also have been associated with warts in nasal, conjunctival, oral, and laryngeal regions. The quadrivalent and nanovalent HPV vaccines each protect against the HPV types that cause 90% of genital warts (i.e., HPV types 6 and 11).[27]

Molluscum contagiosum can be acquired during sexual contact and confused with genital warts. Lesions typically are asymptomatic, 1 to 2 mm, smooth, skin-colored papules. Infections can be transmitted by any skin-to-skin contact, and lesions on nongenital skin are common. The dermatologic lesions of secondary syphilis occur 2 to 6 weeks after initial infection when the primary lesion not diagnosed and treated. Secondary syphilis typically manifests as a diffuse maculopapular rash of the trunk, arms, and legs with a papulosquamous rash involving the palms and soles. Wart-like growths (i.e., condyloma lata) typically appear in the perianal or posterior vulvar area and can be confused with genital warts.

The arthritis and dermatitis syndrome of disseminated gonococcal infection classically includes dermatitis, tenosynovitis, and migratory polyarthritis. Knee, ankle, wrist, and metacarpophalangeal joints are involved most commonly. Dermatitis usually is a painless, maculopapular rash that typically occurs on the trunk and limbs. Tenosynovitis usually involves the hands and fingers and can be asymmetric. More common in young women than men, disseminated gonococcal infection can result from any *N. gonorrhoeae* infection of the genitalia, anus, or pharynx.

For many adolescents, jaundice associated with acute viral hepatitis can be the result of sexually acquired hepatitis A or B virus, cytomegalovirus, or Epstein-Barr virus. Vaccines make hepatitis A and B preventable diseases. Hepatitis C virus is mainly transmitted parentally (i.e., shared needles or paraphernalia) and not efficiently transmitted sexually except for sexually active men with HIV infection.

Scabies is caused by the mite *Sarcoptes scabiei.* Genital infestations can result from sexual contact and may be more difficult to treat in HIV patients. It manifests with rash and pruritus, and clinical symptoms often occur weeks after the initial exposure.

Infestation with pubic lice (*Phthirus pubis*) manifests with itching and lice or nits on pubic hair. Transmission usually occurs through sexual contact.[3]

Skin and Mucous Membrane Infections and Inguinal Lymphadenopathy

Monica E. Patton, Kimberly A. Workowski

In children and adolescents, inguinal lymphadenopathy often occurs as part of generalized lymphadenopathy caused by systemic disease. In contrast, isolated inguinal lymphadenopathy commonly results from localized infections of the groin, buttocks, lower abdominal wall, or lower extremities. Firm or fixed nodes should always raise suspicion for malignancy.

Inguinal Lymphadenopathy With Genital Ulcers

Genital ulcer disease (GUD) frequently manifests as unilateral or bilateral inguinal lymphadenopathy, even when ulcers are not identified clinically. Although GUD can have infectious or noninfectious origins, most cases are caused by sexually transmitted infections (STIs).[1] Prompt diagnosis and treatment of GUD is important to minimize sequelae and decrease transmission of STIs. For example, GUD increases the risk of human immunodeficiency virus (HIV) acquisition and transmission.[2–6] The diagnosis and management of GUD can be challenging because of many possible causes, diverse clinical presentations, and various diagnostic requirements and treatments.[1,7,8]

Etiologic Agents

The most common infectious causes of GUD are herpes simplex viruses (i.e., HSV-2 and HSV-1) and *Treponema pallidum* (i.e., syphilis). Although both are STIs, HSV-1 and HSV-2 also can be spread by nonsexual transmission by caregivers or from autoinoculation.[1,8] Other STIs that cause GUD include *Haemophilus ducreyi* (i.e., chancroid); *Chlamydia trachomatis* serovars L1, L2, and L3 (i.e., lymphogranuloma venereum [LGV]); and *Klebsiella granulomatis* (i.e., donovanosis or granuloma inguinale). With any GUD, regional lymph nodes can become involved and lead to femoral or inguinal adenopathy or ulceration. Infrequently, scabies and pubic lice can cause GUD.

Non-STI infectious GUD causes include varicella-zoster and Epstein-Barr virus infections, tuberculosis, HIV/AIDS, leishmaniasis, secondary bacterial infections, pyoderma, and infections with *Candida* species, *Capnocytophaga* species, *Histoplasma capsulatum, Francisella tularensis*, *Yersinia enterocolitica,* or *Entamoeba histolytica*.[9–13] GUD also can be associated with noninfectious conditions, including fixed drug eruptions, pyoderma gangrenosum, psoriasis, Behçet syndrome, lichen planus, malignancies, aphthae, Lipschütz vulvar ulcers, and Crohn disease.[10,14,15]

Epidemiology of Genital Ulcer Disease Caused by Sexually Transmitted Infections

In the United States, most young, sexually active people with genital, anal, or perianal ulcers have genital herpes or syphilis.[16] Their frequencies vary by geographic area and population. However, genital herpes is more prevalent and is the leading cause of GUD worldwide.[17,18]

HSV infections are lifelong, often asymptomatic, and cause intermittent viral shedding in the genital tract. Most HSV infections are transmitted by people unaware that they are infected.[1] In 2008, an estimated 2.4 million HSV-2 infections occurred among US people between the ages of 15 and 24 years.[19] HSV-1, which typically causes orolabial herpes, is increasingly the cause of genital herpes. The growing numbers of adolescents who lack HSV-1 antibodies at sexual debut likely contributes to the percentage of genital herpes (50%–80%) due to HSV-1 in some populations of young women.[20–22]

Syphilis remains a major US health problem, particularly among men who have sex with men (MSM).[23] Primary and secondary syphilis rates have increased over the past decade, with 75% of all cases occurring among MSM in 2013.[16] Of the 4500 primary and secondary syphilis cases among US persons between the ages of 15 and 24 years in 2013, 86% occurred in males.

The US prevalence of chancroid has declined, with only 10 cases reported in 2013, and it has declined in countries where it was previously endemic.[16,24,25] However, due to the difficulty in detecting *H. ducreyi* in the laboratory, chancroid may be underreported. chancroid infections in the United States are usually associated with sporadic outbreaks.

LGV is endemic in parts of Africa, Southeast Asia, Latin America, and the Caribbean. Since 2003, LGV has also been reported among MSM in the United States, Europe, and Australia. Most men with LGV have had HIV infection associated with high-risk sexual behaviors.[26] Granuloma inguinale occurs rarely in the United States but is endemic in parts of India, the Caribbean, Brazil, Australia, and South Africa.[25]

Clinical Manifestations and Differential Diagnosis

Determining the cause of GUD is challenging based solely on clinical presentation.[1] GUD in children and adolescents requires a thorough history and physical examination to exclude underlying systemic conditions, recent illnesses, or medications and to identify associated factors such as sexual activity or abuse. Frequently, specialized testing is required to establish the cause.

Classic features of GUD are described in Table 50.1. In practice, the causes may be indistinguishable because of coexisting infections, atypical presentations, medication effects, or immunocompromising conditions. Careful examination of the entire genital region, including the perineum and anus, and areas of lymphadenopathy which is facilitated by a good light source and magnifying lens, may improve clinical assessments and guide the choice of diagnostic tests. Anoscopic examinations can identify asymptomatic anorectal manifestations potentially overlooked by the patient and clinician and improve GUD diagnosis and treatment.

TABLE 50.1

Clinical Features of Sexually Transmitted Genital Ulcer Disease Syndromes

Feature	**Herpes Simplex (Herpes)**	***Treponema pallidum* (Syphilis)**	***Haemophilus ducreyi* (Chancroid)**	***Chlamydia trachomatis* (Lymphogranuloma Venereum)**
Estimated incubation period	2–7 days	10–90 days	1–14 days	3–42 days
Site				
Male	Glans, prepuce, penis, anus, rectum	At site of inoculation	At site of inoculation	At site of inoculation (urethral or rectal)
Female	Cervix, vulva, perineum, buttocks, legs, anus, rectum	At site of inoculation	At site of inoculation	At site of inoculation (urethral or rectal)
Typical primary lesion presentation	Vesicle (depends on lesion duration, host immune status)	Papule (ulcerates)	Papule or pustule	Papule, vesicle, vesiculopustular lesion
Number of lesions	Usually multiple; can coalesce, especially in immunocompromised host	Usually single, can be multiple	Often multiple; can coalesce	Usually single
Ulcer appearance	Small, superficial, smooth; with erythematous edge, circular	Superficial, medium size, well demarcated with elevated edge, circular/oval	Deep, small to large; undermined, with ragged edge, irregular shape	Variable depth, small to medium size; elevated edge, round or oval
Induration	None	Firm	Soft	Occasionally firm
Pain	Exquisitely painful	Typically painless	Varies	Varies
Lymphadenopathy characteristic	Firm, tender, often bilateral	Firm, nontender,	Tender, unilateral; can	Large, tender, unilateral; can

		bilateral	suppurate; superinfection	suppurate
Treatment	Acyclovir, valacyclovir, famciclovir, or other acyclovir analogues	Penicillin (dose and duration depend on clinical stage)	Azithromycin, ceftriaxone, ciprofloxacin, or erythromycin	Doxycycline (alternative: erythromycin)

Laboratory Diagnosis and Management

Clinical GUD diagnoses should be confirmed by laboratory testing. A cause is usually identifiable with appropriate specimen collection and testing (Table 50.2), although up to 25% of patients with GUD may not have the cause ascertained.[27] Discussions with laboratory staff can facilitate optimal testing because collection materials, equipment, or appropriate personnel may not available in every laboratory.

TABLE 50.2

Specimen Selection and Laboratory Tests for Diagnosis of Genital Ulcer with Lymphadenopathy Syndrome

Condition	Specimen Type	Test
Herpes	Scraping from ulcer base	Tissue cell culture, PCR
	Serology	HSV-1 and HSV-2 antibodies
Syphilis	Exudate from ulcer	Darkfield microscopy
	Serology	Nontreponemal (with titer quantification); if positive, confirm with treponemal test
Chancroid	Swab from ulcer base or aspirate from bubo	Semiselective media, PCR
Lymphogranuloma venereum	Aspirate from bubo	Tissue culture
	Lesion or swab from ulcer base approved	Direct immunofluorescence, nucleic acid detection for *C. trachomatis*
Donovanosis (granuloma inguinale)	Crush preparation from lesion	Giemsa or Wright stain for Donovan bodies

HSV, herpes simplex virus; PCR, polymerase chain reaction.

All patients with genital, anal, or perianal ulcers should be tested for syphilis and herpes; *H. ducreyi* testing should be performed in settings where chancroid is prevalent.[1] Biopsy can help identify ulcers that do not respond to therapy or are unusual. Because concurrent infections may exist, testing for other STIs is recommended. Thorough risk assessments, counseling, and testing for HIV are important for all people diagnosed with STIs and for those at ongoing risk for infection. Partner counseling and treatment (if indicated) are also recommended as part of comprehensive care. STI diagnoses for children should trigger thorough evaluations for sexual abuse.[1]

The preferred HSV tests for patients with active genital ulcers include viral culture or detection of HSV DNA by polymerase chain reaction (PCR) methods. However, culture sensitivity is low, especially for recurrent lesions, and it declines as lesions heal. PCR is used increasingly because it is more sensitive. Because viral shedding is intermittent, failure to detect HSV by culture or PCR does not indicate an absence of HSV infection. Tzanck preparations are insensitive and nonspecific and should not be used.[1]

Because HSV antibodies develop several weeks after infection and persist indefinitely, type-specific glycoprotein G (gG)–based serologic tests are useful for asymptomatic patients and for patients with negative culture or PCR test results.[1] Determining HSV type influences prognosis and counseling because recurrences and subclinical shedding are less common for genital HSV-1 than genital HSV-2. Repeat testing may be indicated, particularly if recent acquisition of herpes is suspected. Immunoglobulin M (IgM) testing is not useful because IgM tests are not type specific and can be positive during recurrent genital or orolabial HSV infection.

Definitive methods for diagnosing early syphilis include darkfield examinations and tests to detect *T. pallidum* in lesion exudate or tissue.[1] A presumptive syphilis diagnosis is possible with the use of two types of serologic tests: nontreponemal tests (e.g., venereal disease research laboratory [VDRL], rapid plasma reagin [RPR]), and treponemal tests (e.g., fluorescent treponemal antibody, absorbed [FTA-ABS], *T. pallidum* passive particle agglutination [TP-PA], enzyme immunoassays [EIAs]). Using only one type of serologic test is insufficient for diagnosis and can result in false-negative treponemal test results in the primary stages of disease or false-positive nontreponemal test results for persons with certain medical conditions, including HIV infection, autoimmune conditions, pregnancy, and injection drug use.[1]

Optimal GUD management includes empiric treatment for the most likely diagnosis based on clinical presentation and epidemiology (see Table 50.1).[1] Suspected syphilis cases should be treated at the initial visit, even before test results are available, because early treatment decreases transmission. First episodes of genital HSV should be treated presumptively because patients with mild clinical manifestations can develop severe symptoms. The course of HSV can be modified if treatment is started during the prodrome or within 24 hours of symptom onset.[1] Patients should abstain from sexual activity while lesions are present and throughout treatment. If no clinical improvement occurs after treatment, providers should consider other infectious and noninfectious causes or confounding factors, including concurrent STI or HIV infections, reinfection, adequacy of partner treatment, and antimicrobial resistance.[1]

Special Considerations: HIV

HSV-2, syphilis, and chancroid are associated with an increased risk of HIV acquisition and transmission.[2–6] However, GUD treatment has not been effective in preventing HIV acquisition or transmission.[5,28,29] Rates of coinfection with HIV and syphilis or HSV are high, particularly among MSM. In 2013, 35% of US MSM between the ages of 15 and 24 years with primary and secondary syphilis were coinfected with HIV.[23,30,31] Immunocompromised persons with GUD can have prolonged or more severe episodes, have increased transmission, and may require repeated or longer courses of therapy.

Prevention

Prompt diagnosis and treatment of GUDs and other STIs in patients and sexual partners can prevent recurrences and decrease transmission. HSV-2 transmission can be reduced with daily suppressive therapy. Persons should remain abstinent from sexual activity when ulcers are present. Consistent and correct condom use can reduce the risk of GUD and other STIs.[32–34] Male circumcision reduces the risk of GUD.[35]

Inguinal Lymphadenopathy Without

Genital Ulcers

Any infection or inflammation in the groin, lower abdominal wall, or lower extremities can cause inguinal lymphadenopathy without ulcers (Table 50.3), including urinary tract infections, fungal infections, skin infections, appendicitis, and abdominal trauma.

TABLE 50.3

Differential Diagnosis of Inguinal Lymphadenopathy

Condition	Organism	Pattern of Lymphadenopathy	Associations
WITHOUT ULCERS			
Pyogenic bacteria	*Staphylococcus aureus*, group A *Streptococcus*	Suppurative, unilateral, and tender; can progress to abscess	Retrocecal appendicitis, osteomyelitis, pyogenic arthritis, infection of skin or abdominal wall
Cat-scratch disease	*Bartonella henselae*	Unilateral, tender, slowly progressive	Scratch lesion on lower limb
Tuberculosis	*Mycobacterium tuberculosis*	Caseating; can be unilateral, nontender	Miliary tuberculosis, osteomyelitis
Plague	*Yersinia pestis*	Large cluster, very tender nodes	Exposure to fleas, rodents, or rabbits
Tularemia	*Francisella tularensis*	Unilateral, very tender, inflamed	Exposure to rabbits, prairie dogs, rats, sheep, cattle, cats, hamsters, ticks, deerflies, contaminated water or soil
WITH ULCERS			
Herpes	Herpes simplex virus	Bilateral nodes	Sexually transmitted
Syphilis	*Treponema pallidum*	Bilateral nodes	Sexually transmitted
Chancroid	*Haemophilus ducreyi*	Bilateral nodes	Sexually transmitted
Lymphogranuloma venereum	*Chlamydia trachomatis* (L1, L2, L3)	Bilateral nodes	Sexually transmitted
Granuloma inguinale (donovanosis)	*Klebsiella granulomatis*	Bilateral nodes	Sexually transmitted
Tularemia	*Francisella tularensis*	Large, very tender lymph nodes with ulcerated skin lesions	Exposure to rabbit, squirrel, coyote
Mononucleosis	Epstein-Barr virus	Vulvar ulcers with regional adenopathy	—
Yersiniosis	*Yersinia enterocolitica*	Inguinal (unilateral or bilateral)	Fecal-oral route; consumption of pork chitterlings

Other infections can cause acute onset of unilateral inguinal lymphadenitis with occasional progression to abscess formation. *Staphylococcus aureus* and group A *Streptococcus* are the most common causes of suppurative lymphadenitis among children. Patients whose lymphadenitis progresses to abscess formation can come to attention for unexplained limp, inability to extend the leg, and fever, which can mimic septic arthritis or osteomyelitis; right-sided symptoms can suggest retrocecal appendicitis.[36]

Other lymphadenitis causes include anaerobic bacteria, cat-scratch disease (see Chapter 160), and mycobacterial infections (see Chapters 134 and 135).[37–39] Inguinal or femoral buboes can occur in bubonic plague if flea bites occur on the leg (see Chapter 148). Rarely, *Yersinia enterocolitica* infections manifest as inguinal lymphadenitis. Tularemia typically manifests with ulceroglandular syndrome but can manifest as inguinal lymphadenitis (see Chapter 171).

Management of isolated inguinal lymphadenopathy depends on the suspected cause. Lymph node aspiration with smear examination and culture is useful for pyogenic infections. Specific antimicrobial therapy is directed against the inciting pathogen. Further diagnostic investigations, such as ultrasonography or computed tomography, are helpful if osteomyelitis or retrocecal appendicitis is suspected.

Genital Dermatosis

Yeast Infections

Candida albicans or *C. glabrata* (see Chapter 243) commonly cause diaper dermatitis and perineal skin infections. In infants, eruption often starts in the perianal area and spreads to the perineum and upper thighs. Onset can be acute, with scaly macules or papules that coalesce to form well-demarcated, erythematous lesions with irregular borders and satellite lesions. Treatment consists of keeping the area dry and applying topical antifungal cream.

In older children and adolescents, genital candidal infection can involve the vagina or penis. Vulvovaginitis symptoms include pruritus, pain, erythema, and a white discharge (see Chapter 51). Treatment with topical azoles is effective for uncomplicated infections. Balanitis or balanoposthitis can manifest with pruritus, discharge, dysuria, and erythematous lesions with whitish patches on the glans, prepuce, and shaft of the penis. Topical antifungal therapy is effective, but relapses can occur.[40]

Dermatophyte Infections

Excessive perspiration and friction in intertriginous areas such as the groin predispose to superficial infections with dermatophytes, including *Trichophyton rubrum, T. mentagrophytes,* or *Epidermophyton floccosum* (see Chapter 254). These infections are more common in hot weather and occur more often in males. The infection, although often symmetric, can be asymmetric with extension from crural areas to the upper thigh. Erythematous, scaly patches with papular or vesicular margins are typically pruritic, and scratching can lead to lichenification.

Treatment consists of topical antifungals. Systemic therapy (e.g., fluconazole) is occasionally used for widespread or recalcitrant lesions that are common manifestations of candidiasis in immunocompromised patients.

Genital Warts

Genital warts (i.e., condyloma acuminatum) are caused by human papillomavirus (HPV) infection of the epidermis, especially types 6 and 11 (see Chapter 54) (Fig. 50.1). Among adolescents and adults, anogenital warts most often are transmitted sexually. In children, the mode of acquisition is more difficult to assess (see Chapter 56).[1] Pre-exposure vaccination is the most effective method for preventing HPV infection.[41,42]

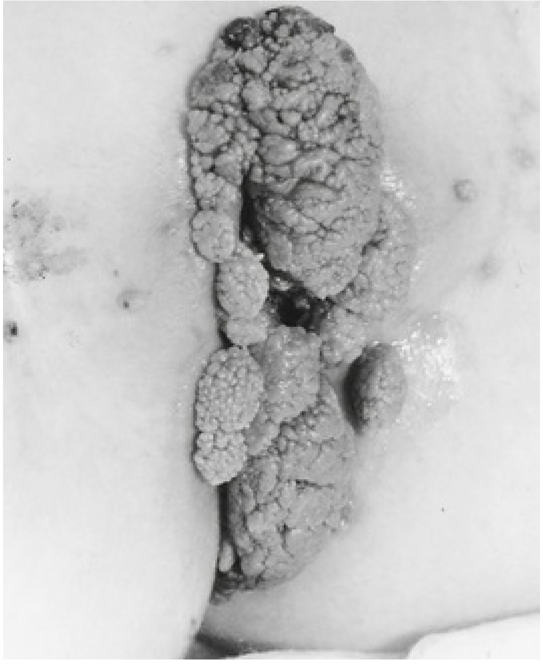

FIGURE 50.1 A 3-year-old girl has large, cauliflower-like genital warts with satellite lesions caused by human papillomavirus infection.

Molluscum Contagiosum Infection

Molluscum contagiosum is caused by parapoxvirus and can be transmitted sexually or nonsexually (see Chapter 202). The incubation period is 2 weeks to 3 months.[40]

Lesions are dome shaped with central umbilication, and the diagnosis is based on the clinical appearance. Although lesions are typically on the face, trunk, and extremities, genital lesions also occur. Unlike genital warts, which occur predominantly on external genitalia, molluscum contagiosum lesions occur most often on the thighs, inguinal region, buttocks, and lower abdominal wall. Lesions can be removed mechanically with curettage or by induction of local inflammation, as with podophyllin application. HIV infection can cause atypical and extensive lesions and should be considered in children and adolescents with multiple lesions, particularly if they occur on the face. Patients should be referred to dermatologic specialists for treatment of extensive infections.

Urethritis, Vulvovaginitis, and Cervicitis

Paula K. Braverman

Urethritis

Urethritis is inflammation of the urethra. The clinical presentation includes dysuria, urinary frequency, and urethral discharge or itching. Neutrophils usually are found in urethral secretions.[1] According to the Centers for Disease Control and Prevention (CDC), urethritis is documented by one of the following: visibly abnormal urethral discharge, a positive leukocyte esterase (LE) test result for a man younger than 60 years of age without other urinary tract disease that could cause pyuria, Gram stain of a urethral smear showing at least 2 white blood cells per high-power field (WBCs/HPF), and a positive LE test result for the first-void urine or 10 or more WBCs/HPF in the first-void urine sediment.[2,3] However, studies have demonstrated that symptoms of urethritis can occur without microscopic evidence of pyuria on the Gram stain of urethral swab specimens or in the first-void urine samples.[4,5]

It may be difficult to establish the diagnosis of urethritis in women because they may not have localized symptoms and some pathogens simultaneously infect multiple genital areas.[6] In the absence of a documented urinary tract infection, female dysuria can represent vulvar inflammation from vaginitis or vulvar dermatoses, interstitial cystitis, or urethral infection with a sexually transmitted infection (STI).[6,7]

Etiologic Agents

Infectious Causes

Organisms associated with STIs are the most significant etiologic agents in urethritis. Newer, more sensitive molecular diagnostic testing modalities for STIs have advanced the understanding of specific pathogens that cause urethritis.

Male Patients.

Chlamydia trachomatis and *Neisseria gonorrhoeae* are common causes of urethritis in men.[1] *N. gonorrhoeae* is estimated to cause one third of acute urethritis cases and is differentiated from other agents, which cause nongonococcal urethritis (NGU).[8] NGU is the most common clinical STI syndrome in men. Rates of specific etiologic agents vary by geography, socioeconomic factors, age, race, and sexual orientation or practices.[1,5,8–14] Coinfection with multiple pathogens can occur, and in 25% to 40% of cases, no pathogen is identified.[15] Approximately 15% to 40% of NGU in men is caused by *C. trachomatis*, 15% to 25% by *Mycoplasma genitalium*, 10% to 20% by *Trichomonas vaginalis,* and 10% to 20% by *Ureaplasma urealyticum*.[15,16]

There has been confusion in the literature regarding the role of *U. urealyticum* as a cause of nongonococcal, nonchlamydial infection in men.[2,5,11,15,17–23] The genus *Ureaplasma* has two types: biovar 1 *(U. parvum)* and biovar 2 *(U. urealyticum)*. Biovar 2 is the biotype most likely associated with urethritis.[15,17–24] Further analysis has revealed that within biovar 2, only specific subtypes may be independently associated with NGU.[18]

T. vaginalis traditionally was considered a less common cause of urethritis in men. However, a nucleic acid amplification testing (NAAT) such as polymerase chain reaction (PCR) and transcription-mediated amplification (TMA) demonstrate that *T. vaginalis* is associated with 10% to 20% of cases of urethritis.[10,15,25–27] *T. vaginalis* can be demonstrated in males without clinical signs of urethritis and commonly is associated with other STIs.[15,28–30]

Herpes simplex virus (HSV) is a less common cause of urethritis in men.[5,11,31] Urethritis develops in 30% of men with primary HSV infection and is found in 2% to 3% of cases of NGU.[15] Studies reported in 2006 found that HSV-1 was responsible for more cases of NGU than HSV-2 and that HSV-1 was more likely to be associated with men engaging in oral-genital sex and men with male partners.[5,11] Infrequent causes of urethritis in men include adenoviruses, *Haemophilus* species, and *Neisseria meningitidis;* coliforms can be an etiologic agent in men who have sex with men (MSM).[1,5,11,15] Identification of some pathogens associated with urethritis suggests that infection with oropharyngeal flora, which are normal nonpathogenic organisms in monogamous partners, is possible.[11]

Nonsexually transmitted NGU is associated with urinary tract infection (UTI), bacterial prostatitis, urethral stricture, phimosis, and urethral catheterization.[1] In 25% to 40% of cases, the cause of NGU in male patients remains unknown.[15]

Female Patients.

Urethritis in female patients can be caused by *N. gonorrhoeae, C. trachomatis,* HSV, and *M. genitalium. T. vaginalis* typically causes vaginitis in women but is known to infect the urethra and is associated with pyuria.[6,7,10,29,32–36]

Noninfectious Causes

In men and women, urethritis can accompany noninfectious systemic diseases such as Stevens-Johnson syndrome, or it can result from chemical irritation.[1,6]

Epidemiology

One half of new STIs occur in adolescents and young adults between the ages of 15 and 24 years.[37] Population-based data for this age group derived from the National Health and Nutrition Examination Survey (NHANES) showed the prevalence of *C. trachomatis* was 1.7% among males and 3.2% among females (2005–2008 data); prevalence of *N. gonorrhoeae* was 0.3% among males and 0.6% among females (1999–2008 data); and prevalence of *T. vaginalis* was 0.9% among males and 1.5% among females (2001–2004 data).[37]

Other studies have demonstrated that prevalence rates of *T. vaginalis* infection increase with age; they are highest among black women, lower among black men, and lowest among whites.[38,39] Similar ethnic or racial differences have been found for *C. trachomatis* and *N. gonorrhoeae*.[40] Data from several studies, including the CDC's 2013 sexually transmitted disease (STD) surveillance report, illustrate that the STI rates vary by specific populations.[25,38,40,41] Youth in correctional facilities and the National Job Training Program have among the highest STI rates.[2,40,41]

Sexual practices and behavior can influence the epidemiology of urethritis. Urethritis due to *C. trachomatis, N. gonorrhoeae,* or HSV among adolescent women correlates with having new sex partners.[6] Adenovirus and HSV-1 have been associated with oral-genital contact and having a male partner, whereas *M. genitalium* and *C. trachomatis* have been associated with vaginal sex.[5] In one study, *N. gonorrhoeae* and *U. urealyticum* urethritis were found in heterosexual men, *C. trachomatis* urethritis was associated with MSM, and *T. vaginalis* was more common in men older than 30 years of age.[42]

Urethritis due to STI pathogens also can occur in prepubertal boys and, less frequently, in prepubertal girls. In this age group, transmission commonly results from sexual abuse with genital-to-genital contact (see Chapter 54).

Clinical Manifestations and Differential Diagnosis

Symptomatic urethritis in adolescent males is characterized by dysuria, urethral discharge, or urethral pruritus. Discharge can be mucoid, mucopurulent, or purulent. Gonococcal urethritis compared with NGU usually has a shorter incubation period, more acute onset, and more profuse discharge (Table 51.1).[1] Discharge in patients with NGU can be so scant that it is only noticed in the morning or is apparent as crusting on the meatus or as stains in underwear.[1] Urethral infection with *N. gonorrhoeae* and the various organisms causing NGU also can be asymptomatic.[43]

TABLE 51.1

Clinical Manifestations of Nongonococcal and Gonococcal Urethritis

Characteristic	Nongonococcal Urethritis	Gonococcal Urethritis
Incubation period	2–3 weeks	2–6 days
Onset	Insidious	Abrupt
Dysuria	+, may wax and wane	++, continuous
Discharge	Scant to moderate, may be absent	Profuse, absent in <10%

+, modest discomfort; ++, more severe discomfort.

Urethritis must be differentiated from UTI, particularly in adolescent boys with dysuria but no discharge. In contrast to UTI, frequency, hematuria, and urgency are uncommon in urethritis. However, if the male adolescent is sexually active, pyuria is more likely to be caused by urethritis than UTI because UTI is uncommon in this age group. A focused STI history (see Chapter 49) and thorough medical history can help establish relative risks of urethritis and UTI.

In adolescent girls, dysuria is the cardinal feature of urethritis, which must be differentiated from acute bacterial cystitis and vulvovaginitis (Table 51.2). The literature differentiates *internal* and *external* dysuria. Internal dysuria is pain that is felt internally during voiding. External dysuria is discomfort that is felt as urine passes over the labia.[7] Internal dysuria, urinary frequency, and isolation of more than 10^2 uropathogens per milliliter of voided urine suggest acute bacterial cystitis; isolation of 10^2 or fewer uropathogens per milliliter suggests acute urethritis due to STI pathogens.[6] Pain that is felt internally only at the end of urination is consistent with bacterial cystitis.[7] External dysuria can occur with vulvovaginitis. Female adolescents can have vaginitis alone or a concurrent UTI and may not be able to adequately distinguish between internal and external dysuria.[7,44] Any female patient suspected of having urethritis requires an STI-directed history and physical examination to identify other STIs or STI syndromes (e.g., pelvic inflammatory disease [PID]).

TABLE 51.2

Distinguishing Features of Urethritis, Acute Bacterial Cystitis, and Vulvovaginitis in Adolescent Females

Feature	Urethritis	Acute Bacterial Cystitis	Vulvovaginitis
Symptoms	Internal dysuria	Internal dysuria, frequency, urgency, hematuria	External dysuria, vaginal discharge, vulvar burning, itching
Duration of symptoms	Often ≥7 days	Usually ≤4 days	Varies with cause

Signs	Mucopurulent cervicitis Vulvar lesions	Suprapubic tenderness	Vulvar lesions and inflammation, vaginal discharge
Epidemiologic associations	New sex partner Previous STI Sexual partner with STI	Previous cystitis Onset of symptoms within 24 hours of intercourse Use of diaphragm Use of a spermicide	History of genital herpes Sex partner with genital herpes Antibiotic use Previous vulvovaginitis Candidiasis

STI, sexually transmitted infection.

Modified from Holmes KK, Stamm WE, Sobel JD. Lower genital tract infection syndromes in women. In: Holmes KK, Sparling PF, Mardh P-A, et al. (eds). Sexually Transmitted Diseases, 4th ed. New York, McGraw-Hill, 2008, pp. 987–1016.

In prepubertal boys and girls, urethritis due to STI pathogens can manifest with dysuria and urethral or vaginal discharge. There may be vague lower abdominal pain, unwillingness to void, and in boys, irritation in the distal urethra or meatus. Dysuria in a prepubertal child is much more likely to be caused by UTI than urethritis associated with STI. Urethritis is more probable in the setting of a discharge or a history of sexual abuse, especially if genital-to-genital contact has occurred.

Laboratory Findings and Diagnosis

Male Patients.

For male patients, specimens are obtained to document urethritis and to detect common causes such as *N. gonorrhoeae* and *C. trachomatis*. The definitive diagnosis is enhanced if the patient has not voided recently; examination in the morning before voiding is ideal.[1] A meatal swab specimen of a discharge can be taken for Gram stain; the finding of gram-negative intracellular diplococci of the typical kidney bean morphology pattern (Fig. 51.1) or at least 2 neutrophils per oil immersion field (×1000) is diagnostic of urethritis.[1,2] A Gram stain smear is sensitive and specific in diagnosing gonococcal urethritis if intracellular diplococci are detected. If the Gram stain is equivocal, negative, or unavailable and the criteria for urethritis are met, NAAT for *N. gonorrhoeae* and *C. trachomatis* is indicated.[2]

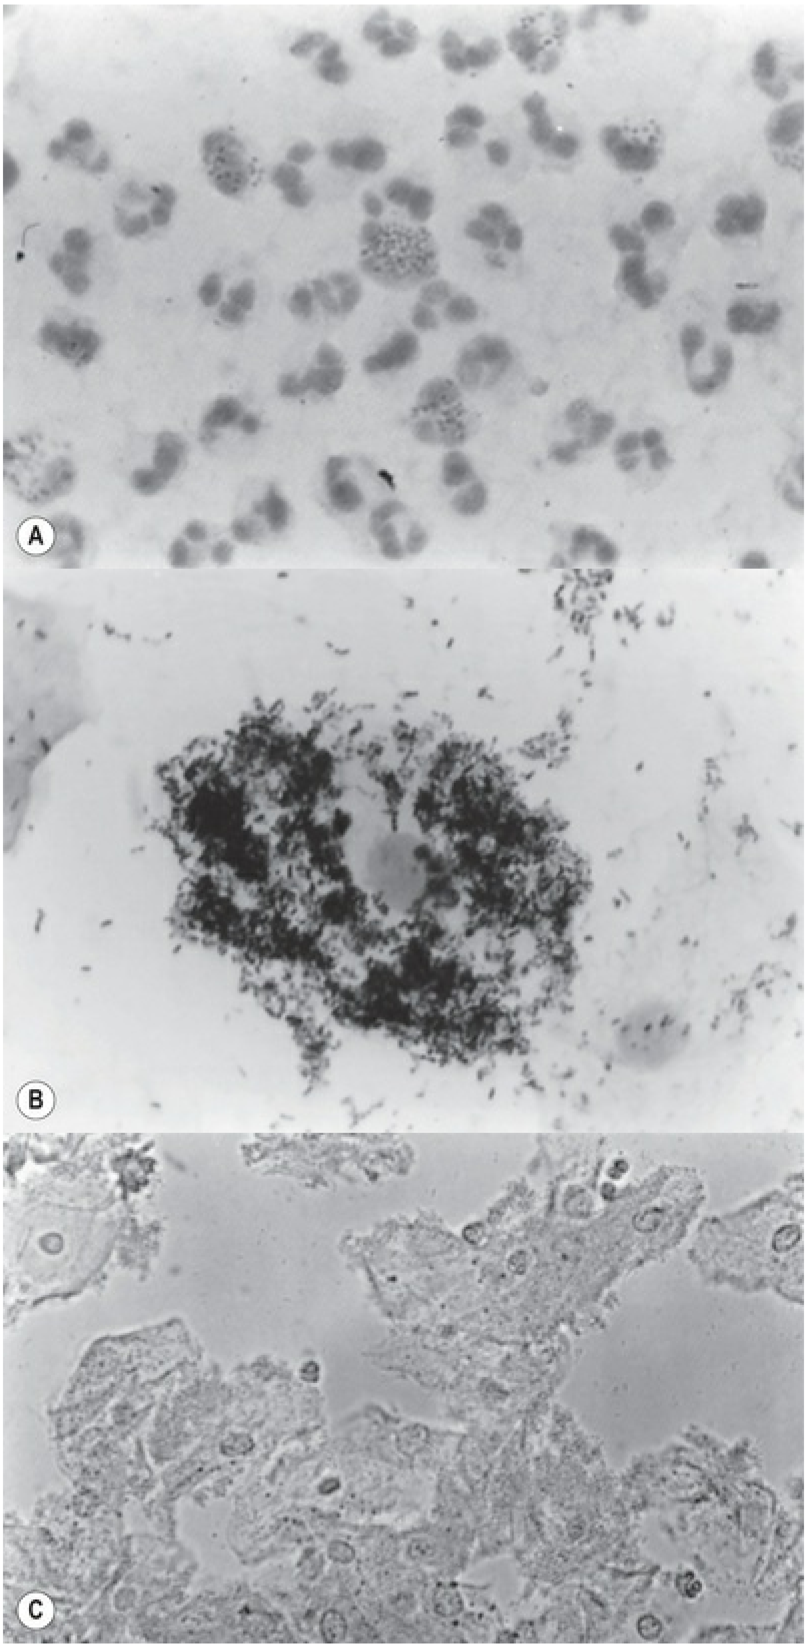

FIGURE 51.1 (A) Gram stain of urethral discharge from an male adolescent with urethritis shows multiple neutrophils and intracellular diplococci with the kidney-bean morphology typical of *Neisseria gonorrhoeae* (magnification ×1000). (B) Gram stain of vaginal fluid from an adolescent with bacterial vaginosis shows clue

cells and squamous vaginal epithelial cells covered with coccobacilli, which gives them a stippled or granular appearance. Notice the absence of rods with blunt ends (i.e., lactobacilli) (magnification ×2000). (C) Wet mount of vaginal secretions from a female adolescent with bacterial vaginosis shows clue cells. Notice the stippled epithelial cells with ragged (i.e., bacteria-covered), ill-defined borders (magnification ×200).

In all patients, regardless of whether *N. gonorrhoeae* is suspected by Gram stain, a first-voided urine or urethral specimen should be obtained for detection of *C. trachomatis* by NAAT. The optimal specimen from male patients is a first-voided urine.[2,45] NAAT for *N. gonorrhoeae* and *C. trachomatis* may detect infection in male patients with symptoms of urethritis but no objective evidence of urethral inflammation.[2]

The diagnosis of *T. vaginalis* in men is more challenging than in women. Wet mount preparation of a urethral smear detects only 30% of *T. vaginalis* infections in men.[28] Culture can be performed on urine, semen, or urethral specimens and appears to yield better results if multiple sites are tested.[2,29,46] The InPouch culture system (BioMed Diagnostics, San Jose, CA) is equivalent to the gold standard Diamond media, and urethral or urine sediment specimens can be inoculated.[25] However, studies have shown that NAAT is superior to a wet mount preparation or culture to detect *T. vaginalis* in male patients.[10,26,28,29,47–49] Although the TMA test is approved only in the United States for female specimens, it may be used in laboratories that have conducted validation procedures on male specimens.[2,46,50] *T. vaginalis* PCR is not commercially available. Specific testing of men for *T. vaginalis* should be considered for cases of nongonococcal urethritis in high-prevalence areas or populations.[2]

Cultures for *U. urealyticum* are not available readily, and *M. genitalium* is difficult to isolate.[1,32,51] In research studies, both are diagnosed and evaluated using NAAT. However, these tests are not cleared for use by the US Food and Drug Administration (FDA), and management relies on the clinical presentation and exclusion of other causes.[2]

Female Patients.

Endocervical or vaginal and urethral specimens should be obtained for NAAT for *N. gonorrhoeae* and *C. trachomatis* in adolescent girls with urethritis because concurrent infection is common.[2,6] Urinalysis and urine culture also are indicated because simultaneous UTI and STI can occur in sexually active females.[7] Urine testing using NAAT for *C. trachomatis* and *N. gonorrhoeae* is not as sensitive as endocervical specimen testing.[2,45] Studies using NAAT for vaginal specimens have shown good correlation with cervical specimens, and the vaginal specimens can be collected by the healthcare personnel or the patient.[2,45]

T. vaginalis can be diagnosed by a variety of methods, including wet mount preparation, culture, nucleic acid probe, immunochromatographic capillary flow dipstick technology, and NAAT.[2,25,48,49,52,53] As for male patients, wet mount microscopy has poor sensitivity compared with other methods.[2] NAAT for *T. vaginalis* (e.g., strand displacement amplification [SDA]), and TMA are FDA cleared for use in women for endocervical, vaginal, or urine specimens.[2,48,52]

Treatment

Initial treatment for male patients can be based on Gram stain results (Table 51.3).[2] Patients with evidence of *N. gonorrhoeae* by Gram stain should be treated with dual single-dose therapy, including intramuscular ceftriaxone and oral azithromycin to reduce the development of antimicrobial-resistant *N. gonorrhoeae.* Although oral cefixime can be substituted for ceftriaxone, it is not the first-line drug due to resistance patterns and poor efficacy if there is a concomitant pharyngeal infection.[2]

TABLE 51.3

Recommended Treatment of Urethritis in Postpubertal Children and Adolescents

	Gram Stain	Suggested Treatment
RESULTS AVAILABLE		
Increased Neutrophils	Gram-Negative Intracellular Diplococci	

Present	Present[a]	Treat for gonococcal and chlamydial urethritis. For *Neisseria gonorrhoeae:* for postpubertal children >45 kg and adolescents, ceftriaxone (250 mg IM once) or cefixime (400 mg PO once) *and* azithromycin (1 g PO once) For *Chlamydia trachomatis:* for postpubertal children ≥8 years and adolescents, azithromycin (1 g PO once) *or* doxycycline (100 mg bid PO for 7 days)
Present	Absent	Treat for nongonococcal urethritis. Azithromycin (1 g PO once) *or* doxycycline (for 7 days) *or* ofloxacin (300 mg PO bid for 7 days) *or* levofloxacin (500 mg PO once daily for 7 days) *or* erythromycin base (500 mg PO qid for 7 days) *or* erythromycin ethylsuccinate (800 mg PO qid for 7 days)
Absent	Absent	Defer treatment until microbiologic results are available, or if patient is high risk by history and follow-up cannot be ensured, treat for gonococcal and chlamydial urethritis
RESULTS NOT AVAILABLE		
Urethral discharge	—	Treat for gonococcal and chlamydial urethritis
No urethral discharge	—	Defer treatment until microbiologic results are available, or if patient is high risk and follow-up cannot be ensured, treat for gonococcal and chlamydial urethritis
RECURRENT OR PERSISTENT URETHRITIS		
—	—	Azithromycin (1 g PO once) if not used for initial episode; for failure, moxifloxacin (400 mg PO qd for 7 days) to cover *Mycoplasma genitalium*; metronidazole (2 g PO once) or tinidazole (2 g PO once) to cover *Trichomonas vaginalis*

[a] Gram stains are considered inadequate to evaluate prepubertal children for *N. gonorrhoeae*.

IM, intramuscularly; IV, intravenously; PO, orally.

Data from Workowski KA, Bolan GA. Sexually transmitted diseases treatment guidelines, 2015. MMWR Recomm Rep 2015;64(RR- 3):1–137.

All patients with negative Gram stain results should be tested for *C. trachomatis* and treated if positive. For NGU, a single dose of azithromycin may be preferred over a 1-week course of doxycycline in adolescents because of adherence.[2] Single-dose azithromycin is also preferred because it is most effective in treating *M. genitalium*, which is the most common cause of persistent and recurrent NGU.[2] Confirmed cases of *N. gonorrhoeae* or *C. trachomatis* must be reported to the local health authorities, and sexual partners should be contacted for assessment and treatment.

Immediate follow-up and repeat testing for *N. gonorrhoeae* or *C. trachomatis* urethritis in adolescents are not recommended routinely if appropriate treatment is completed, signs and symptoms disappear, and no re-exposure to an untreated partner occurs. However, because of the high rate of reinfection after initial treatment, repeat testing for *N. gonorrhoeae* and *C. trachomatis* is recommended in 3 months.[2] If symptoms persist despite good adherence and no re-exposure and the person meets diagnostic criteria for persistent or recurrent NGU, further management is indicated. Treatment without signs for urethral inflammation has not been demonstrated to be effective.[2,54,55]

M. genitalium is the most common cause of persistent or recurrent NGU.[2] If doxycycline was used initially, single-dose azithromycin should be tried because it is more effective than multidose doxycycline for this organism.[2] However, resistance has developed to azithromycin, and studies have demonstrated treatment failure in men treated with both single-dose and extended-dosing regimens of azithromycin, possibly related to the selection of resistant organisms with the common use of single-dose azithromycin for treatment of *N. gonorrhoeae* and *C. trachomatis*. Seven days of moxifloxacin (400 mg daily) is effective for treatment failures for *M. genitalium*.[2,16,51,54–57] Fluoroquinolone resistance has also been demonstrated.[57,58]

For male patients with persistent urethritis, culture of a urethral specimen or first-void urine for *T. vaginalis* should be performed because of the high prevalence of *T. vaginalis* infection among men with nongonococcal, nonchlamydial urethritis and coinfection with these organisms. If there has been laboratory validation, testing of urethral or urine specimens with NAAT is preferred.[2] If *T. vaginalis* is diagnosed, metronidazole or tinidazole is prescribed (see Chapter 274). Current CDC guidelines recommend presumptive treatment with metronidazole or tinidazole in cases of persistent urethritis in areas of high prevalence for men who have sex with women.[2] *U. urealyticum* can be difficult to eradicate, and resistance to tetracyclines has been demonstrated.[1,51] Patients who do not respond to therapy should be referred to a urologist.

Female patients with findings suggesting bacterial cystitis can be treated presumptively for UTI. However, if urethritis is suspected, a single dose of azithromycin (1 g) or a 7-day course of doxycycline (100 mg twice per day) is indicated pending results of urine culture and STI testing.[2] If symptoms of dysuria due to vulvovaginitis are found, treatment should be directed at the cause. Although the CDC's 2015 STD treatment guidelines do not specifically discuss persistent urethritis in females, treatment of *M. genitalium* should be considered when other causes have been ruled out, and ideally, testing for this organism should be done.[35]

Complications

Complications of urethritis include disseminated gonococcal infection (0.5% to 3%) and reactive arthritis syndrome (i.e., Reiter syndrome). In male patients, epididymitis (1% to 2%) and, rarely, prostatitis and balanoposthitis also occur.[1,16] Female patients with *N. gonorrhoeae*, *C. trachomatis*, and *M. genitalium* infection also are at risk for PID and infertility.[7,16,36,59] *M. genitalium* has been associated with preterm birth and spontaneous abortion.[2,59] In male and female patients, STIs associated with urethritis increase susceptibility to infection with, viral shedding, and transmission of HIV.[2,60,61]

Prevention

Correct and consistent use of condoms is the most effective means of preventing and reducing transmission of the STIs associated with urethritis.

Vulvovaginitis

Vulvovaginitis (i.e., inflammation of the vagina or vulva) is a common gynecologic problem in prepubertal and adolescent girls. The cause, pathogenesis, and management are substantially different for the two age groups.[7] Vaginitis and vulvitis are a continuum in young children, whereas they are distinct clinical entities in adolescents.

Vulvovaginitis in Prepubertal Girls

Etiologic Agents and Epidemiology

Prepubertal girls can have specific or nonspecific vaginal infections.[7] Several factors predispose young girls to vulvovaginal irritation, including proximity of the vagina to the rectum, poor hygienic practices, lack of protective labial fat pads and pubic hair, and lack of an estrogen effect on vaginal mucosa.[7,62] Prepubertal girls are more likely than postpubertal girls to experience vulvar irritation and trauma from soaps, bubble baths, and clothing.[7] The lack of estrogen effect in prepubertal girls promotes an environment with a neutral pH, predisposing to overgrowth with a variety of potential pathogens.[6,62] Vaginal microbial infections that are not STIs usually are caused by respiratory tract and enteric pathogens.

T. vaginalis is rare in prepubertal children because lack of estrogen makes the vagina resistant to this infection.[7] Isolation of *Gardnerella vaginalis* in prepubertal vaginitis is not diagnostic of bacterial vaginosis (BV) but has been reported in prepubertal girls after sexual assault.[7] *Candida* vulvovaginitis is not common in prepubertal girls unless there are other risk factors, such as antibiotic use, diabetes mellitus, immunosuppression, or use of diapers; 3% to 4% of prepubertal girls have *Candida* spp. as part of normal vaginal flora.[7,62]

Although prepubertal vulvovaginitis is not often sexually transmitted, sexual abuse must be considered if pathogens such as *C. trachomatis, N. gonorrhoeae, T. vaginalis,* human papillomavirus (HPV), or HSV are identified.[7,62] Attributing HPV to sexual abuse rather than vertical transmission or inoculation from caregivers and autoinoculation is challenging because of the lack of studies in this age group regarding incubation, latency to clinical presentation, and cutoff ages for vertical transmission.[62] Similar to the cervical epithelium of postpubertal girls, the cuboidal vaginal epithelium of prepubertal girls is susceptible to *N. gonorrhoeae* and *C. trachomatis.*[6] Other causes of vulvovaginitis include foreign body, vulvar skin disorders, and allergic reactions (Box 51.1).

Box 51.1

Etiologic Factors in Prepubertal Vulvovaginitis

Nonspecific Causes

Contact or Allergic Reactions (Common)

- Bubble-bath preparations
- Shampoos, soaps
- Laundry detergents
- Clothing (e.g., nylon undergarments)

Physical Factors (Common)

- Foreign body
- Sand (e.g., sandbox)
- Poor hygiene (e.g., wet diapers)

Specific Microbiologic Causes

Not STI Related

- *Shigella* spp.
- *Yersinia enterocolitica*
- Enteric bacilli
- *Staphylococcus aureus*
- Group A *Streptococcus*
- *Haemophilus influenzae*
- *Enterobius vermicularis*
- *Moraxella catarrhalis*
- *Streptococcus pneumoniae*
- *Neisseria meningitidis*
- *Candida* spp.

Possibly STI Related (Less Common)

- *Neisseria gonorrhoeae*
- *Chlamydia trachomatis*
- *Trichomonas vaginalis*
- Herpes simplex virus

Vulvar Skin Disorders

- Eczema
- Psoriasis

STI, sexually transmitted infection.

Clinical Manifestations, Differential Diagnosis, and Clinical Approach

The clinical features of vulvovaginitis in children include vaginal discharge, vulvar irritation, pruritus, dysuria, bleeding, genital inflammation, and foul smell.[7,62] When associated with a foreign body, the discharge can be profuse, foul smelling, and blood tinged.[7] Parents often are unaware that the child has inserted something into the vagina. In *Enterobius vermicularis*–associated vulvovaginitis, recurrent symptoms and vulvar or anal pruritus are common. Discharge can be bloody in cases of vulvovaginitis caused by *Shigella* spp. or *Streptococcus pyogenes* infection.[6,7,62] Bleeding also should raise concern about trauma. Diffusely hyperemic vulvar mucosa suggests streptococcal vulvovaginitis. Discharge associated with gonococcal infection is commonly green and purulent, whereas discharge is less common with chlamydial infection.

All prepubertal children with vulvovaginitis require a careful history and physical examination. Vaginitis due to *S. pyogenes* can occur after a pharyngeal or skin infection in the patient or family members. Finding a sibling with an STI raises concern about sexual abuse by someone associated with the family.[7,62] Gynecologic examination includes abdominal inspection and palpation. In a gentle and supportive manner, inspection of the perineal skin, vulva, and perirectal and genital areas is performed to detect excoriation, erythema, ulcers, or structural abnormalities. Visualization of the vagina and cervix without instrumentation usually is possible with the patient in the knee-chest position.[7] This facilitates detection of a foreign body, especially if a magnifying lens or otoscope head is used. Examination with the patient under anesthesia may be necessary in some cases.

Laboratory Findings and Diagnosis

Samples of a vaginal discharge are obtained (Box 51.2) using a sterile, saline-moistened swab for potassium hydroxide (KOH) preparation, Gram stain, and culture.[62] A vaginal wash using nonbacteriostatic saline or vaginal aspiration using an eyedropper are alternative methods of specimen collection.[7,62] However, the latter specimens may not be as sensitive for identification of *C. trachomatis* if few epithelial cells are collected, which are necessary because the organism is an obligate intracellular pathogen. Culture confirmation of *N. gonorrhoeae* and *C. trachomatis* is the most admissible legal evidence for cases of suspected sexual abuse.

Box 51.2

Testing Vaginal Discharge or Aspirate Specimens From Prepubertal Girls With Vulvovaginitis

Gram stain for bacteria and white blood cells[a]

Culture for aerobic and anaerobic bacteria

Culture for *Neisseria gonorrhoeae* and *Chlamydia trachomatis*[b]

Wet mount to detect clue cells[c] or trichomonads[d]

Potassium hydroxide preparation to detect fungal elements[d] and note odor

Scotch tape specimen from perianal area in early morning if pinworms are suspected

---

[a] Gram stain should not be used to diagnose or exclude *N. gonorrhoeae* in prepubertal children.

[b] Nonculture tests usually are not recommended in cases of abuse due to the risk of false-positive results, but nucleic acid amplification testing (NAAT) of vaginal or urine specimens may be an acceptable alternative particularly in other circumstances.

[c] Clue cells are stippled epithelial cells whose borders are obscured by adherent bacteria.

[d] Culture also can be performed for *Trichomonas vaginalis* and yeast. NAAT for *Trichomonas vaginalis* has not been adequately studied in prepubertal children.

NAAT for vaginal or urine specimens may be an alternative to culture for testing of vaginal secretions in girls.[2] *T. vaginalis* can be detected in vaginal wash specimens or by culture.[7,53] If *Enterobius* infestation is suspected, the parent is instructed to examine the perianal region at night for the small, white pinworms, and a Scotch tape swab or paddle specimen is collected from the perianal area immediately on the child's awakening. Samples for culture for yeast should be considered if itching persists or the history suggests risk factors for candidal infection.[7,62]

Treatment

The mainstay of treatment for nonspecific vulvovaginitis is education, attention to personal hygiene, and avoidance of agents such as bubble baths and tight nylon undergarments that provoke the problem.[62] Sitz baths in warm water without soap may be helpful. Vitamin A and D ointment or petroleum jelly can protect the vulva, and a short course of 1% hydrocortisone cream can alleviate acute exacerbations of irritant vulvitis.[7,62] In severe cases, an estrogen cream may be applied for several weeks to ameliorate symptoms.[7,62] If a foreign body is detected, removal usually resolves the problem.

Treatment of vulvovaginitis due to specific pathogens is initiated on the basis of the Gram stain, wet mount preparation, culture, or NAAT results. Recommended treatments for *N. gonorrhoeae* are ceftriaxone alone for patients who weigh 45 kg or less and ceftriaxone along with azithromycin for those who weigh more than 45 kg. For *C. trachomatis*, erythromycin is given to patients who weigh less than 45 kg, azithromycin for those younger than 8 years of age and who weigh 45 kg or more, and azithromycin or doxycycline for older girls. For *Candida*, an antifungal agent, such as clotrimazole, is used, or oral fluconazole is used if topical therapy is not effective. Treatment for *S. pyogenes* is penicillin or amoxicillin. Other antimicrobial agents are chosen on the basis of vaginal bacterial culture results.[2,7,62]

Complications

The follow-up of children with vulvovaginitis depends on the cause. Fortunately, gonococcal and chlamydial vulvovaginitis rarely are associated with upper tract disease, and impairment of fertility is unlikely if the infection is treated adequately.[7] For recurrences due to *S. pyogenes,* pharyngeal colonization in the patient and carriage in family members are considered.[62]

Vaginitis in Pubertal Girls

Etiologic Agents and Epidemiology

Under the influence of estrogen at puberty, the vaginal epithelium shifts from cuboidal to a glycogen-containing stratified squamous epithelium, and there is an associated increased growth of lactobacilli that produce lactic acid and hydrogen peroxide.[6,7,63] This results in a decrease in vaginal fluid pH from a prepubertal level of about 7.0 to about 4.0. Changes in the epithelium, colonizing flora, and pH render the vaginal environment relatively resistant to infection caused by *C. trachomatis* and *N. gonorrhoeae.* In adolescents, these two organisms cause cervicitis rather than vulvovaginitis.

Leukorrhea, the normal white mucous vaginal discharge that represents the effect of estrogen on the vaginal mucosa in adolescents, must be distinguished from pathologic discharge. Saline wet mount examination of vaginal secretions reveals sheets of epithelial cells without inflammatory cells, yeast, clue cells, or trichomonads. Leukorrhea sometimes is considered excessive by patients, and they need reassurance.[7,63]

The major causes of vaginitis in adolescents are BV, candidiasis, and *T. vaginalis* infection. BV has replaced the term *nonspecific vaginitis* because the condition usually is not inflammatory but arises from a change in the vaginal flora.[7,64] Less common causes of vaginitis in adolescents include ulceration and infection associated with tampons, cervical caps, vaginal contraceptive ring, and other foreign bodies; chemical agents such as those found in douches and spermicides; and toxin-producing *Staphylococcus aureus.*[6,7,65]

Bacterial Vaginosis.

BV is the most common cause of vaginitis in postpubertal women, affecting approximately one third of women.[63,66–68] BV represents a disruption in the normal vaginal flora, with a decrease in lactobacilli and overgrowth of a variety of primarily anaerobic organisms. BV-associated organisms include *G. vaginalis,* genital mycoplasmas *(M. hominis), U. urealyticum, Bacteroides, Prevotella, Porphyromonas, Peptostreptococcus, Fusobacterium,* and *Mobiluncus* species.[63,64,69–71] Although many patients with BV have moderate to heavy concentrations of vaginal *Gardnerella* species, detection of this organism is not diagnostic because vaginal colonization is common in patients without BV and not specific for the diagnosis.[63,64,71]

New technologies employing amplification of ribosomal RNA are being used to characterize bacterial species that are not identified by culture [64,70–72] They include three clostridial bacteria, *Leptotrichia* and *Megasphaera* species, and Eggerthella-like bacteria.[70–72] In one study, detection of these noncultivatable bacteria had excellent sensitivity and specificity for diagnosing BV compared with standard diagnostic criteria.[71]

In a multivariate analysis of NHANES data from 2001 through 2004, risk factors for BV included a higher number of lifetime sex partners, douching, low educational achievement, and being non-Hispanic black.[68] BV has also been associated with poverty, smoking, having a female sex partner, high body mass index, and previous pregnancy.[68,73,74] The prevalence of BV among women attending STI clinics is higher (30% to 37%) than among college students (4% to 15%)[7] and the prevalence of BV in a nationally representative sample of 14-19 year old women was 18.5%.[68]

BV is more common among adolescents and young adults who are sexually active and have multiple sexual partners. However, designating BV as an STI has been controversial because some studies have found BV in sexually inexperienced females.[64,66,68,75,76] One study of women entering the military found that 19% of subjects denying a history of vaginal intercourse met criteria for BV compared with 28% who had been active sexually.[75] Another study questioned the accuracy of sexual histories having failed to find BV in truly sexually inexperienced college students.[77] Studies have shown a concordance between the presence of *G. vaginalis* in the urethra of male sex partners of women diagnosed with BV but did not find this organism in male controls.[64] Sexual activity, multiple sexual partners, receptive oral sex, and vaginal insertion of sex toys that were not cleaned are associated with BV, whereas the use of condoms appears to be protective.[64,73,74,77–80] Treatment of sex partners does not appear to prevent recurrence.[64] However, a systematic review of randomized, controlled trials of male partner treatment for BV criticized these studies for having methodologic flaws.[81]

Up to one third of women experience recurrent episodes of BV within 3 months of treatment.[66] In one study, factors associated with recurrence over a 12-month period included a history of BV and having a female sex partner or a regular sex partner.[82] Recurrence may be related to reinfection from an infected partner or to failure to re-establish lactobacilli dominance with persistence of pathogenic bacteria.[63,67,72] Some investigators have postulated that the recurrence of BV is related to persistence of a biofilm containing *G. vaginalis* and other organisms that adheres to the epithelial cells and provides protection from systemic and topical antibiotics.[72,83–85]

Candidiasis.

Vulvovaginal candidiasis has an estimated lifetime incidence of up to 75%.[86] Candidal colonization of the vagina usually originates from the gastrointestinal tract, and sexual transmission is not an important mode of acquisition.[2,63,86] As many as 30% of healthy asymptomatic women are colonized with yeast, and *Candida albicans* is the organism found in most uncomplicated cases.[63,66] Risk factors include pregnancy, poorly controlled diabetes, immunosuppression, receptive oral sex, use of estrogen, and use of various contraceptives, including intrauterine devices, diaphragms, vaginal rings, and possibly spermicides.[63,65,66,86] Antibiotic use is mentioned frequently, but it is not a major cause of infection in most women. Rather, colonization by species of *Candida* may place a subpopulation of women at higher risk for symptomatic infection.[66,86–88] For approximately one half of girls and women, no risk factors are identified.[63,66]

Most women experience uncomplicated vulvovaginal candidiasis, with infrequent mild to moderate episodes caused by *C. albicans*.[86] However, 10% to 20% of women have complicated vulvovaginal candidiasis that is more severe, recurrent, or caused by other *Candida* species. These women are more likely to have underlying medical risk factors such as diabetes or immunocompromise.[2,86] Approximately 5% of women have recurrent disease (i.e., ≥4 episodes in a 12-month period), which is more likely to be associated with *C. glabrata* and other non-*albicans Candida* species.[2,66,86,89] Most women with recurrent vulvovaginal candidiasis do not have diabetes mellitus or immunosuppression, but these conditions increase the risk. It is postulated that some patients may have a genetic predisposition to recurrent vulvovaginal candidiasis, suppression of local immunity due to virulence factors produced by the *Candida* species, or an alteration in local innate response leading to an aggressive inflammatory leukocytic response to yeast colonization.[63,66,86,90,91]

Trichomonas vaginalis.

T. vaginalis is the third most common cause of infectious vaginitis and has a worldwide distribution, with prevalence in community-based studies ranging from 2% to 46% of women.[10,63] It is the most prevalent curable STI worldwide, with most cases found in women.[27] In the United States, an estimated 3.7 million people are infected.[37]

Studies using PCR testing of urine or vaginal swabs from girls and women between the ages of 14 and 26 years have shown *T. vaginalis* prevalence rates of approximately 2% to 3%, which was higher than the rate for gonorrhea among the same people.[52] Certain populations may have a higher prevalence, including 26% of symptomatic and 7% of asymptomatic women at STI clinics, up to 18% of patients at adolescent clinics, 10% of women in college health programs, and up to 47% of incarcerated women.[2,10,52] Other risk factors include being African American, smoking, using alcohol and drugs, having multiple partners, and adolescents having an older sexual partner.[2,10] *T. vaginalis* facilitates transmission and acquisition of HIV and commonly is associated with other STIs.

Clinical Manifestations and Differential Diagnosis

Clinical presentations that help differentiate BV from candidal vulvovaginitis and trichomonal vaginitis are shown in Table 51.4. In the sexually active adolescent, cervicitis also must be excluded because it can occur as a coinfection or as the sole cause of the vaginal discharge.[92]

TABLE 51.4

Characteristics and Recommendations for Treatment of Vaginitis in Adolescents

---

	Bacterial Vaginosis	Candidal Vaginitis	Trichomonal Vaginitis
SYMPTOMS			
Odor of vaginal discharge	Malodorous	Usually not malodorous	May be malodorous
Vulvar itch	Sometimes	Yes or discomfort	Yes
Dysuria	Sometimes	Yes	Yes
Dyspareunia	Sometimes	Yes	Yes
Other symptoms	No	Symptoms often exacerbated before menses	No
SIGNS			
Appearance of vaginal discharge	Thin, homogeneous, white, clings to vaginal wall, ± frothy	Thick, curd-like	Heavy, grey or yellow-green, frothy
Other signs	No	Vulvar and vaginal erythema, vulvar edema	Vulvar and vaginal erythema
LABORATORY FINDINGS			
pH	>4.5	<4.5	>4.5
KOH preparation	Fishy, amine odor when mixed with 10% KOH (positive whiff test)	Hyphae or pseudohyphae	Occasionally positive whiff test
Saline preparation	Clue cells, few neutrophils	Neutrophils and epithelial cells in equal numbers	Motile trichomonads, neutrophils
Gram stain	Few gram-positive bacilli; abundant mixed flora	Hyphae or pseudohyphae or blastospores	Trichomonads visualized rarely
Culture	Not useful	Can be useful if KOH negative	Culture more sensitive than wet mount
TREATMENT			
	Oral Metronidazole (500 mg bid for 7 days) *or* clindamycin (300 mg bid for 7 days) *or* tinidazole (2 g qd for 2 days) *or* tinidazole (1 g qd for 5 days) **Topical intravaginal** Clindamycin cream 2% (one full applicator amount per vagina at bedtime for 7 days) *or* clindamycin ovules (100 mg per vagina at bedtime for 3 days) Metronidazole 0.75% gel (one full applicator amount per vagina qd for 5 days)	**Topical intravaginal**[a] Butoconazole cream Clotrimazole cream Miconazole cream or vaginal suppository Terconazole cream or vagina suppository Tioconazole ointment **Oral** Fluconazole (150 mg once)	**Oral** Metronidazole (2 g for 1 dose *or* 500 mg bid for 7 days) *or* tinidazole (2 g in a single dose)

[a] Intravaginal therapies are available in 1- to 14-day regimens.

KOH, potassium hydroxide.

Symptomatic BV manifests with a thin, white-grey, homogeneous vaginal discharge that adheres to the vaginal walls and has a fishy odor.[64,66] Women with symptomatic candidal infection commonly complain of vaginal pruritus and burning, dysuria, and dyspareunia. Discharge can be thick and white with a cottage cheese appearance or can be watery and homogeneous. Discharge usually is not malodorous, and in many cases, women do not notice a change in vaginal discharge.[66,86] Patients with symptomatic trichomoniasis often have pruritus and a malodorous, frothy, yellow or greenish discharge and can have dysuria, abdominal pain, vulvar erythema and edema, and bloody vaginal discharge. Cervicitis can occur, with punctuate hemorrhages (i.e., strawberry cervix) and friability. Asymptomatic *T. vaginalis* infection occurs commonly.[10]

Laboratory Findings and Diagnosis

Laboratory features that help distinguish BV from candidal vulvovaginitis and trichomonal vaginitis are shown in Table 51.4.

Bacterial Vaginosis.

The diagnosis of BV is commonly established in the clinical setting by the finding of three or more of the following Amsel criteria: (1) thin, homogeneous vaginal discharge; (2) vaginal pH >4.5; (3) characteristic fishy or amine odor released when 10% KOH is added to the vaginal fluid specimen (i.e., positive whiff test); and (4) 20% or more of epithelial cells having the appearance of clue cells, which are stippled epithelial cells whose borders are obscured by adherent bacteria (see Fig. 51.1).[64] Diagnostic accuracy increases with use of the Amsel criteria.[25] Alternative tests include the use of Gram stain to group bacteria into morphologic types (i.e., Nugent scoring). Amsel criteria and Nugent scores show good correlation.[2,93]

Alternative testing includes nonmicroscopic point-of-care testing. Some tests detect the metabolic products of BV-related organisms such as sialidase and prolineaminopeptidase.[2,64] A DNA probe for *G. vaginalis* ribosomal RNA is available but is not useful if rapid results are needed. This test is most helpful as a supplemental marker to detect high concentrations of *G. vaginalis*.[22,93]

Routine aerobic and anaerobic vaginal cultures are not helpful, and molecular diagnostic techniques are primarily a research tool.[2,67] BV usually does not produce an inflammatory response, and the finding of WBCs on a vaginal smear indicates concurrent vaginitis or cervicitis due to another cause.[92,93]

Candida species.

Candida vaginitis is diagnosed by demonstrating budding, hyphae, pseudohyphae, or blastospores on microscopic examination of a saline or 10% KOH preparation.[2,63] This technique has a sensitivity of about 50% because organisms such as *C. glabrata*, which does not form hyphae or pseudohyphae, are easily missed on microscopy.[2] If the KOH preparation is negative, culture can confirm the diagnosis in symptomatic people.[67,86] Culture may be particularly helpful for patients with ongoing nonspecific symptoms in whom BV and trichomoniasis have been excluded.[86] In cases of complicated vulvovaginal candidiasis, culture is important in identifying the species of the organism because therapy may be different or longer.[63,94] Culture can also demonstrate eradication of the organism, and for patients with persistent symptoms, an alternative cause should be investigated.[63,94] It is useful to measure vaginal pH because the vaginal pH remains low (<4.5) in vaginal candidiasis, unlike BV or trichomoniasis.[86]

Trichomonas vaginalis.

Diagnosis of trichomoniasis can be made by visualizing the motile protozoa on a wet mount preparation; however, the test result is negative in 30% to 50% of cases.[2,67] Culture using Diamond media or the InPouch *T. vaginalis* culture system is more sensitive.[2,25,67] Culture can be performed on vaginal specimens, including patient self-collected specimens.

Conventional and liquid Papanicolaou (Pap) tests are not considered diagnostic because of high false-positive and false-negative rates.[2,95] A DNA probe test has a sensitivity of 63% and specificity of 99% compared with culture and TMA. It usually is best performed in the laboratory rather than the office setting because the test is moderately complex and requires about 45 minutes to complete.[2]

One point-of-care test that uses an immunochromatographic capillary flow assay with monoclonal antibodies takes 10 minutes to complete and has 82% to 95% sensitivity and 97% to 100% specificity.[2] PCR has excellent sensitivity and specificity (85% to 100%) but is not available commercially.[10] TMA has 95% to 100% sensitivity and 95% to 100% specificity and is approved for endocervical, urine, and vaginal swab specimens in women.[2,47,48] NAAT using SDA is approved for use with female endocervical, vaginal, and urine specimens.[2]

Because urine or vaginal specimens collected without use of a speculum can be used to detect trichomoniasis, vulvovaginal candidiasis, *N. gonorrhoeae*, and *C. trachomatis*, it is possible to avoid the more invasive speculum examination to determine the cause of vaginitis in adolescents.

Management

Bacterial Vaginosis.

Metronidazole administered orally for 7 days is the recommended therapy for women with symptomatic BV,[2] and it is preferred over single-dose therapy because of superior efficacy.[2,25,64,69] Alternative regimens with intravaginal metronidazole or clindamycin, which are outlined in Table 51.4, have fewer gastrointestinal side effects and cure rates similar to those for oral metronidazole at 1 month after treatment.[2,25,67,69] Clindamycin cream should not be used when condoms are used because the oil base weakens the latex.[2] Alternate therapeutic regimens have included the use of tinidazole, which has fewer side effects than metronidazole but is more expensive, and oral clindamycin.[2,66,96]

A Cochrane review found insufficient evidence to recommend for or against probiotics. The 2015 STD treatment guidelines do not recommend this therapy or currently available lactobacillus formulations as adjunctive or replacement therapy to restore normal vaginal flora.[2,97]

There are no current standard recommendations for treatment of recurrent BV infection, which occurs within 3 months in approximately one third of women.[69] Treatment may only suppress biofilm-embedded infection and allow organisms to evade host defense responses. Recurrences may be due to relapse rather than reinfection.[67,69,85] A large, multicenter study demonstrated the 70% efficacy of twice-weekly maintenance therapy using metronidazole vaginal gel, but it only suppressed BV in many subjects and led to vaginal candidiasis as a complication.[98,99] One uncontrolled study showed promising results with nitroimidazole and boric acid used to disrupt the biofilm and allow penetration of the antibiotic.[100] Other regimens that have been evaluated include oral nitroimidazole and intravaginal boric acid followed by suppressive metronidazole gel and a combination of monthly oral metronidazole and fluconazole.[100,101] The latter regimen was associated with decreased BV episodes and increased colonization with normal flora.

Long-term treatment with vaginal metronidazole is well tolerated, unlike oral treatment, which can be associated with neutropenia or peripheral neuropathy. Prolonged treatment with clindamycin increases the risk of *C. difficile* colitis.[69] Resistance to metronidazole and clindamycin has been seen in cases of recurrent BV.[68] The 2015 STDs treatment guidelines do not recommend treating asymptomatic nonpregnant women.[2]

Candidiasis.

Topical therapy with azoles, such as clotrimazole, terconazole, miconazole, butoconazole, and tioconazole, is effective for vulvovaginal candidiasis in 1- to 7-day regimens. Many of these topical formulations are available over the counter. Single-dose fluconazole (150 mg) therapy has efficacy that is comparable to topical therapy.[2,63,66,102] Symptomatic relief and negative fungal cultures are achieved in up to 90% of patients with uncomplicated vulvovaginal candidiasis. Sexual partners usually do not require therapy unless they have candidal balanitis.[2]

Recurrent or chronic candidal vulvovaginitis merits investigation for predisposing conditions, which includes obtaining cultures to confirm the diagnosis and identify the pathogen.[63] These infections may require a longer duration of topical (7 to 14 days) or oral therapy including nonfluconazole imidazole drugs.[2,66,67,86] Topical boric acid in the form of suppositories (600 mg in a gelatin capsule) and topical flucytosine have been useful in patients with non-*albicans Candida* species and imidazole-resistant species. Alternative therapies are useful, especially in cases of non-*albicans Candida* species.[66,86,94] When using fluconazole, patients with recurrent vulvovaginal candidiasis can be treated initially with a single dose every 3 days for a total of three doses, followed by 100 mg, 150 mg, or 200 mg once each week for 6 months.[2] For women who cannot take fluconazole, repeated topical imidazole therapy has been effective.[2,66,67]

Suppressive therapy usually is continued for 6 months, but recurrence is common after therapy is discontinued because organisms are suppressed rather than eradicated. Prophylaxis can be reinstituted.[2,63,86] Fluconazole resistance and clinical failure is uncommon but increasing, and although not usually warranted, in patients with breakthrough *Candida* infection, susceptibility testing may be helpful.[2,103] Only topical azole medications are recommended in pregnancy.[2]

Trichomonas vaginalis.

Systemic therapy with oral metronidazole or tinidazole is indicated for treatment of trichomoniasis.[2] Metronidazole has an 84% to 98% cure rate with a 7-day course (500 mg twice daily) or a large single dose (2 g taken orally). Most recurrent infections are from reinfection, and although uncommon, metronidazole resistance has been reported in approximately 4% to 10% of cases.[2,49,67,69] Topical therapy with metronidazole gel is not effective because the gel does not penetrate the urethral and perivaginal glands adequately.[2,10,49]

Single-dose tinidazole (2 g taken orally) has a 92% to 100% cure rate and reports of 1% resistance.[2] Studies show tinidazole to be equivalent or superior to single-dose metronidazole for cure and symptom resolution.[2] One study found a 92% cure rate using a combination of oral and vaginal tinidazole in patients unresponsive to metronidazole.[104] Tinidazole appears to be better tolerated than metronidazole and has fewer gastrointestinal tract and central nervous system side effects.

Sexual partners should be evaluated for STIs and treated for trichomoniasis. For treatment failures, susceptibility testing is recommended for metronidazole and tinidazole.[2,49] Women with HIV infections should be treated with metronidazole for 7 days rather than single-dose therapy because the latter is less effective in these patients due to concurrent BV, impaired immunity, and concurrent antiretroviral therapy, which may impact clearance and reduce the efficacy of metronidazole.[2,105] There are no contraindications to using metronidazole during pregnancy, but tinidazole should not be used because of concerns about moderate adverse risks.[2]

Complications

Bacterial Vaginosis.

BV has been associated with chorioamnionitis, postpartum endometritis, posthysterectomy vaginal cuff cellulitis, postabortion PID, premature rupture of membranes, preterm labor and delivery, low birth weight, spontaneous abortion, and intra-amniotic infection.[25,64,76,106] The risk of preterm delivery is restricted to a small subset of women; risk may be related to the genetic host response to inflammation and cytokine production.[25,64,76] Vaginal microorganisms can ascend to the upper tract, causing infection and inflammation in the decidua, chorioamnion, or amniotic fluid.[64]

Data are conflicting about whether the treatment of pregnant women for BV prevents complications.[2,25,64,76,107–110] Two systematic reviews found little evidence that screening and treating all pregnant women prevents preterm birth.[108,109] The evidence for screening asymptomatic women at low risk for preterm delivery were poor, and evidence for women at high risk for preterm delivery were conflicting. The 2015 STD treatment guidelines state that the evidence is insufficient to recommend screening of asymptomatic pregnant women at low or high risk for preterm delivery, but they do recommend treatment for all symptomatic pregnant women using any oral or vaginal regimen.[2]

BV has been associated with an elevated risk of acquiring *T. vaginalis*, *N. gonorrhoeae*, *C. trachomatis*, and HSV-2.[2,109,111] Studies also have shown an association between BV and cervicitis and PID, but a causal relationship remains unproved.[64,66] Organisms associated with BV have been found in the upper genital tracts of women with PID. Studies using endometrial biopsies have found an association between BV and endometritis, which may be silent clinically or manifest as intermenstrual or increased bleeding.[64]

Women with BV are more likely to have PID, and women with PID are more likely to have BV.[25,64,76] Treatment of BV has been associated with decreased PID in women undergoing abortion and decreased postoperative cuff cellulitis.[64,76] Intravaginal treatment of BV has been associated with improved rates of resolution of cervicitis.[64] However, the relationship between BV and PID for women not undergoing abortion or uterine instrumentation is not clear.[25,76,112] There is no current recommendation for treatment of nonpregnant, asymptomatic women as a standard clinical practice.[2,64]

Trichomonas vaginalis.

Trichomoniasis has been associated with premature rupture of membranes, preterm delivery, and low-birth-weight infants,.[2,25,113] *T. vaginalis* has also been associated with an increased risk of PID in women who are HIV positive.[2,113] Although treatment of *T. vaginalis* during pregnancy does not appear to reduce complications, the 2015 CDC STD treatment guidelines recommend that all symptomatic pregnant women should be tested and considered for treatment at any stage of pregnancy.[2,107,114] Although a single dose of metronidazole has been demonstrated to be safe at all stages of pregnancy, more studies are needed regarding use of tinidazole, and current recommendations recommend avoiding use in pregnancy.[2]

Human Immunodeficiency Virus.

BV and *T. vaginalis* enhance acquisition of HIV and transmission to a partner.[2,25,29,64,76,105,115] Vulvovaginal candidiasis has been associated with increased HIV seroconversion in HIV-negative women and higher levels of cervicovaginal HIV shedding in HIV-positive women. Treatment of *T. vaginalis* reduces HIV viral shedding in vaginal secretions.[105] However, no studies have demonstrated similar effects on viral shedding in subjects with BV or vulvovaginal candidiasis.[2,25]

Vulvitis in Adolescents

Inflammation of the vulva in adolescents most commonly is caused by HSV and yeasts (see Table 51.4). HSV often causes painful genital ulcers, along with vulvar inflammation and inguinal lymphadenopathy (see Chapter 50).[7] Occasionally, inflammation can be associated with *T. vaginalis* infection.

Prevention

Correct and consistent use of condoms is the most effective means of preventing and reducing transmission of the STIs associated with vulvovaginitis.

Cervicitis

Cervicitis is inflammation of the endocervix or ectocervix. Both are common problems among adolescents, but neither is common in prepubertal girls. Under the influence of estrogens after puberty, the vaginal epithelium and ectocervix become cornified and relatively resistant to infection with a number of pathogens, including *N. gonorrhoeae* and *C. trachomatis*.[7] In contrast, the endocervix continues to be lined with columnar epithelium and remains susceptible to infection with these organisms. In adolescents and adult women, these organisms usually cause endocervicitis in the absence of vaginitis.

A normal developmental finding in adolescents is the ectropion, an erythematous area surrounding the os at the junction between columnar and stratified squamous epithelium. During adolescence, the ectropion recedes as the result of squamous metaplasia. Although some adolescents with a large ectropion may have significant vaginal discharge, this is not a pathologic or infectious process. The ectropion usually is not friable, and edema or friability suggests infection.[6]

Ectocervicitis

Ectocervicitis represents infection of the stratified squamous epithelium of the ectocervix. Ectocervicitis can occur in conjunction with trichomonal vaginitis and HSV infection. HSV causes ectocervicitis and endocervicitis.[6]

Endocervicitis

Etiologic Agents and Epidemiology

Endocervicitis represents infection of the endocervical columnar epithelium and can produce mucopurulent cervicitis. Common pathogens that cause endocervicitis are *N. gonorrhoeae*, *C. trachomatis*, *M. genitalium*, and HSV.[6,116–119] Multiple studies have demonstrated an association between *M. genitalium* and mucopurulent cervicitis.[16,33,36,59,116–118,120–123] There also is a possible association with BV because cervicitis is more likely to resolve when patients also are treated for BV.[25,116–118,120] Theories about this relationship include proinflammatory vaginal cytokines in patients with BV and the glycosidases and proteinases produced by BV-associated organisms that may degrade cervicovaginal mucus.[116,117]

The prevalence of cervicitis varies from 22% to 41% depending on the definition used, which is inconsistent among the various studies in the literature.[116] A randomized, multicenter study that ruled out *C. trachomatis*, *N. gonorrhoeae*, *T. vaginalis*, and *M. genitalium* by NAAT found that 61% of subjects had mucopurulent cervicitis of unknown origin.[124]

Clinically apparent cervicitis is not caused solely by sexually transmitted agents. Other entities include tuberculosis, noninfectious causes such as sarcoidosis and Behçet disease, and local insults due to chemical douches, spermicides, and foreign bodies.[116–119]

Clinical Manifestations and Differential Diagnosis

Endocervicitis often is overlooked and underdiagnosed because signs and symptoms can be mild or absent. PID is one consequence of untreated mucopurulent cervicitis.[6] Sexually active adolescents with vaginal discharge, lower abdominal pain, abnormal vaginal bleeding, or deep dyspareunia should be evaluated for endocervicitis.[6] Evaluation also is indicated if a sexual partner has an STI.

Cervical abnormalities associated with endocervicitis range from subtle changes to a yellow endocervical discharge and an edematous, erythematous, and easily friable appearance to the cervix.[6] There is no consensus definition for mucopurulent cervicitis, which makes evaluation of the research literature difficult.[116,117] Definitions include inflammation of the endocervix with possible edema, yellow-green endocervical discharge, increased numbers of neutrophils on microscopic examination of cervical secretions, and inducible endocervical bleeding.

The 2015 CDC STD treatment guidelines outline the two major diagnostic criteria as purulent or mucopurulent endocervical discharge and sustained endocervical bleeding.[2] Mucopurulence is characterized by a yellow or green color on a cotton-tipped applicator obtained from the endocervix. The number of neutrophils considered significant varies in different studies from at least 30 cells per 400× magnified microscopic field to more than 10 cells per 1000× magnified microscopic field. Although the use of a 30-cell cut point provides greater specificity, detection of yellow endocervical mucopus is more accurate than the number of WBCs.[2,6,117–119]

Laboratory Findings and Diagnosis

Specific microbiologic diagnosis informs appropriate treatment. Patients should be tested for *N. gonorrhoeae, C. trachomatis, T. vaginalis*, and BV. Gram-negative intracellular diplococci are seen on Gram stain in about one half of cases of gonococcal endocervicitis.[6] Given the poor sensitivity of the Gram stain and the possibility of infection in the absence of any abnormality, evaluation for gonococcal endocervicitis must include NAAT.[2] Inflammatory changes can be even less remarkable with endocervicitis caused by *C. trachomatis*. NAAT is recommended in all cases of suspected *C. trachomatis* infection.[2] A saline wet mount preparation can be used to diagnose *T. vaginalis* and to help establish the diagnosis of BV.[2,6,7,117] Because of the poor sensitivity of wet mounts, further testing for *T. vaginalis* by culture, antigen-based tests, or NAAT should be conducted if the wet mount result is negative.

If HSV is suspected, a culture or PCR test should be obtained, although the utility of HSV testing remains unknown.[2] NAAT for *M. genitalium* is not available commercially but may be available in laboratories where validation testing has been completed.[2]

Treatment

The initial management of endocervicitis depends on the clinical findings and risk of the adolescent for certain STIs (Table 51.5). A positive laboratory test result for *N. gonorrhoeae, C. trachomatis, T.*

vaginalis, or HSV defines treatment. However, empiric treatment can be considered if there is a strong suspicion of *N. gonorrhoeae* or *C. trachomatis* based on a high prevalence of either microbe in the community or a concern that the patient may be at risk for loss to follow-up.[2,120]

TABLE 51.5

Treatment of Cervicitis in Adolescents

Results	Suggested Treatment
Mucopurulent or purulent endocervical discharge and/or sustained easily induced endocervical bleeding	Treat for *Chlamydia trachomatis or Neisseria gonorrhoeae* with positive test results *or* consider presumptive treatment for *C. trachomatis* and *N. gonorrhoeae* if prevalence is high in patient population or community (e.g., known contact, new and/or multiple sex partners, age ≤25, unprotected sex) and testing not possible and/or follow-up cannot be ensured; if at low risk for STIs, treatment can be deferred pending microbial results
Trichomonas seen on wet mount or identified on rapid test, culture, NAAT	Treat with oral metronidazole or tinidazole
Bacterial vaginosis diagnosed	Treat with oral metronidazole *or* tinidazole *or* intravaginal metronidazole *or* clindamycin
Clinical presentation suggesting herpes simplex virus infection	Consider oral acyclovir *or* famciclovir *or* valacyclovir
Persistent or recurrent cervicitis	Rule out re-exposure or treatment failure for *N. gonorrhoeae* and *C. trachomatis* or other identified STIs and exclude BV. Testing for *Mycoplasma genitalium* in settings with validated assays can be conducted. Moxifloxacin can be used if NAAT results are positive and initial treatment with azithromycin (1 g PO once) failed. CDC recommends deferring therapy until further microbial results are available[a]

[a] Data from Workowski KA, Bolan GA. Sexually transmitted diseases treatment guidelines, 2015. MMWR Recomm Rep 2015;64(RR-3):1–137.

BV, bacterial vaginosis; CDC, Centers for Disease Control and Prevention; NAAT, nucleic acid amplification test, STIs, sexually transmitted infections.

BV should be treated because some studies have shown higher rates of resolution of endocervicitis with treatment of BV.[117] For women at lower risk for STIs, treatment can await the results of diagnostic testing.[2]

More data are needed about the treatment of *M. genitalium* cervicitis. The antibiotics directed at treating *N. gonorrhoeae* and *C. trachomatis* are not adequate to treat cervicitis caused by other organisms, and the standard treatment regimen for PID with cefoxitin and doxycycline is ineffective for women with *M. genitalium* associated with PID.[120,125,126] Testing for *M. genitalium* is recommended for women with persistent cervicitis or persistent PID for whom re-exposure to an infected partner or nonadherence has been ruled out.[2,35,116] If the initial treatment did not include azithromycin, the antibiotic should be given. According to CDC guidelines, moxifloxacin can be given based on having positive *M. genitalium* test results.[2] Other investigators have suggested considering this treatment for recurrent or persistent cervicitis when testing is not available,[35] but some have questioned the treatment of cervicitis of unknown origin because the clinical cure described is not related to antibiotic therapy.[127]

The need to consider *M. genitalium* in the adolescent population was demonstrated in several studies. One showed a cumulative rate over a 27-month period among 14- to 17-year-old girls to be 14%, which was concordant with their male partners.[128] Another study of girls and women 14 to 21 years old found a rate of 22%.[129]

Follow-up after completion of therapy is recommended for adolescents with persistent symptoms.[2] The management of mucopurulent cervicitis also requires evaluation and treatment of all sexual partners for STIs, and it provides an opportunity to reinforce STI prevention measures.[2]

Complications

Complications of untreated mucopurulent cervicitis include PID and the possible long-term sequelae of ectopic pregnancy and infertility. The relationship between *N. gonorrhoeae* or *C. trachomatis* and PID is well established, and there is increasing evidence that *M. genitalium* also is associated with PID.[6,59,118,130–132] Cervicitis also increases the risk of transmission and acquisition of HIV infection. Viral shedding of HIV decreases with effective treatment for cervicitis.[2,6,118]

Prevention

Consistent use of condoms can reduce transmission of STI pathogens associated with cervicitis.

Pelvic Inflammatory Disease

Eloisa Llata, Harold C. Wiesenfeld

Pelvic inflammatory disease (PID) is an ascending, polymicrobial genital tract infection that is considered to be the sequela of a sexually transmitted disease (STD) due to *Chlamydia trachomatis* or *Neisseria gonorrhoeae* and endogenous microorganisms from the lower genital tract (i.e., vagina and cervix). PID can include endometritis, salpingitis, tubo-ovarian abscess, or pelvic peritonitis. Morbidity from PID includes chronic pelvic pain, ectopic pregnancy, and tubal-factor infertility.

Over the past several decades, rates of PID have declined in hospital and ambulatory settings in the United States.[1,2] Although no single factor explains this trend, increases in chlamydia screening, use of more sensitive diagnostic technologies, and availability of single-dose therapies for uncomplicated lower genital tract infections may be responsible.[1–3] Despite declining trends, sexually active adolescents have among the highest age-specific rates of PID, potentially impacting future fertility.[1,4] Risk factors, including biologic and behavioral predispositions, barriers to healthcare, poor compliance, and issues surrounding confidentiality, make this age group especially vulnerable.[5]

Epidemiology

The US incidence estimates provided by the Centers for Disease Control and Prevention (CDC) in 2001 indicate that approximately 750,000 cases of PID are diagnosed annually, with 20% occurring among sexually active girls younger than 19 years.[4] High-risk sexual behavior among adolescents, including engaging in unprotected sex, having multiple sex partners, age discrepancy of partners, early sexual debut, drug or alcohol abuse, and having serially monogamous relationships of short duration and high frequency, have been identified as risk factors.[6–8] Young adolescent women have a cervical transitional zone of columnar epithelium (i.e., ectropion) that is the targeted attachment site of *C. trachomatis* and *N. gonorrhoeae*.[9]

Contraceptives play an important role in modulating the risk of PID. Nonuse of contraception is a risk factor for PID, whereas barrier methods decrease the risk of STD acquisition and subsequent development of PID.[10,11] Most studies that evaluate the role of oral contraceptive pills demonstrate a protective role, which may result from thickening of the cervical mucus, shorter duration of menses, or a decreased receptivity of the endometrium to infection.[9,12–14]

Intrauterine devices (IUDs) have had limited use among the adolescent population due to concerns about the increased risk of PID and STDs. Modern IUDs do not increase the risk of PID beyond the risk associated with insertion of the device, nor do they increase the risk of STD acquisition.[15,16] The American Congress of Obstetricians and Gynecologists supports the use of the IUD as a first-line agent in adolescents and women who have never been pregnant.[17] Douching also has been implicated, and although the elevated risk may be caused by an alteration of the vaginal flora or mechanical flushing of organisms into the upper genital tract, the exact mechanism is unknown.

A prior history of PID or another STD is a recognized risk factor for PID. The increased risk observed may reflect reinfection from untreated partners, relapse from inadequate therapy for the first infection, increased vulnerability to subsequent gram-negative or anaerobic bacterial infection, or continued presence of other risk factors. Estimates that almost one third of female adolescents diagnosed with PID return with a subsequent STD or PID within 6 months of their original treatment highlights that reinfection is likely to be extremely common in this group.[18]

Etiologic Agents

C. trachomatis and *N. gonorrhoeae* have been isolated from the lower and upper genital tracts in women with PID and are accepted universally as etiologic agents of PID. Estimates from the PID Evaluation and Clinical Health (PEACH) study found that approximately 40% of women diagnosed with PID had cervical *C. trachomatis* or *N. gonorrhoeae* infection.[19] *Chlamydia* is the most commonly reported STD in the United States, with more than 1 million reported female cases in 2014.[20] Women between the ages of 20 and 24 years had the highest incidence of reported *Chlamydia* infection (3651 per 100,000), and girls between the ages of 15 and 19 years had the second highest incidence (2941 per 100,000).[20]

Data from prospective studies suggest that about 15% of untreated chlamydial infections progress to clinically diagnosed PID.[21,22] *Chlamydia* infection has been associated with tubal scarring, obstruction, and peritubal adhesions.[23–25] Evidence demonstrates that *C. trachomatis* infection is particularly important in *subclinical or silent PID*, a term used to describe women with lower genital tract infections and concurrent endometritis or salpingitis but with mild or no symptoms. Subclinical PID is estimated to account for 50% or more of all PID cases.[9]

N. gonorrhoeae is the second most commonly reported bacterial STD, with incidence reaching 569 cases per 100,000 US girls between the ages of 15 and 19 years in 2014.[20] Women younger than 25 years of age are at the highest risk for acquiring gonorrhea, and between 10% and 20% of women with inadequately treated gonococcal cervicitis will develop PID.[26]

Endogenous microorganisms associated with bacterial vaginosis (BV), a disruption of the normal vaginal microflora leading to an overgrowth of anaerobic and facultative bacteria, have been recovered from the upper genital tract in women with acute PID. Many investigations have demonstrated an association between BV and acute PID,[19,27–34] concluding that BV facilitates the ascending spread of vaginal microorganisms and provides an inoculum of potentially pathogenic microorganisms. Sexually transmitted *Mycoplasma genitalium* also has emerged as a likely cause of cervicitis, endometritis, salpingitis, and infertility, but research is needed to further investigate the importance of this organism.[35,36]

Pathogenesis and Pathologic Findings

The ascent of *C. trachomatis* and *N. gonorrhoeae* from the cervix through the endometrium to the fallopian tubes is the most common antecedent to PID. After infection-induced inflammation reaches the fallopian tube, a complex interaction of epithelial degeneration, edema, and other inflammatory responses occurs, leading to scarring of the fallopian tube (Fig. 52.1).[37] The presence of other bacteria may be explained by priming of tissue by the STD organisms (i.e., monomicrobial phase) for opportunistic invasion by facultative and anaerobic bacteria from the lower genital tract (i.e., polymicrobial phase).[38] Priming can result from alteration of local mucosal defenses or anatomic interference with mechanical host defenses that drain secretions from the upper genital tract mucosa.

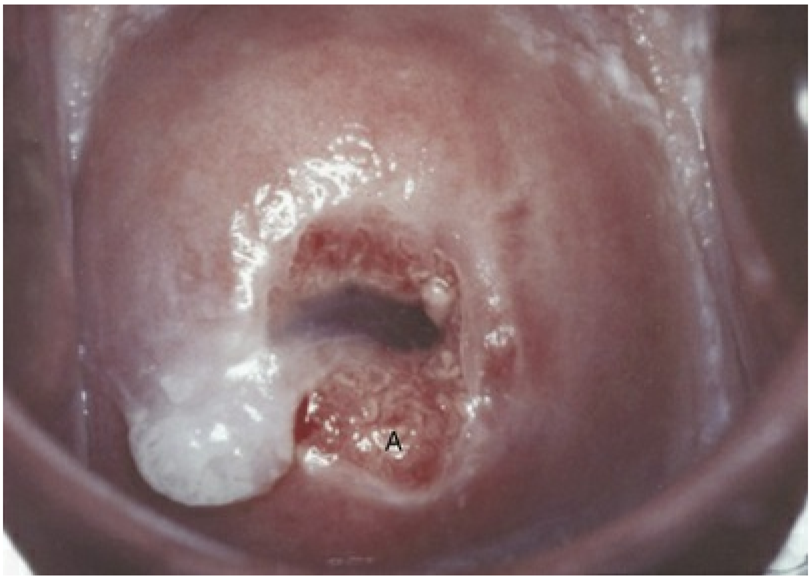

FIGURE 52.1 Examination of an adolescent girl shows an area of cervical ectopy (*A*), where the columnar cells that line the inner area of the cervix extend to the outer area.

Diagnosis

Despite published guidelines (Box 52.1), the clinical diagnosis of PID is challenging because of variations in clinical presentation. Studies have documented suboptimal healthcare personnel adherence to recommended guidelines for the diagnosis of PID.[39,40] Diagnosing PID in female adolescents can pose unique challenges because they may be unable to recognize their symptoms, may be reluctant to reveal their sexual activity, or may forgo the use of medical care because of the stigma of having an STD. Clinicians need to recognize the implication of mild or nonspecific findings, particularly in a girl giving a challenging history and undergoing her first pelvic examination.[41]

Box 52.1

CDC Guidelines for the Clinical Diagnosis of Pelvic Inflammatory Disease

Minimum Criteria

Cervical motion tenderness *or* uterine tenderness *or* adnexal tenderness

Empiric treatment of PID should be initiated in sexually active young women and others at risk for STIs if ≥1 of the minimum criteria exist and no other causes for the illness can be identified.

Additional Criteria

Oral temperature >38.3°C (>101°F)

Abnormal cervical or vaginal mucopurulent discharge

Abundant numbers of WBCs on saline microscopy of vaginal secretions

Elevated erythrocyte sedimentation rate

Elevated C-reactive protein level

Laboratory documentation of cervical infection due to *Chlamydia trachomatis* or *Neisseria gonorrhoeae*

Definitive Criteria

Endometrial biopsy with histopathologic evidence of endometritis

Transvaginal sonography or magnetic resonance imaging techniques showing thickened, fluid-filled tubes with or without free pelvic fluid or tubo-ovarian complex, or Doppler studies suggesting pelvic infection (e.g., tubal hyperemia)

Laparoscopic abnormalities consistent with PID

CDC, Centers for Disease Control and Prevention; PID, pelvic inflammatory disease; STIs, sexually transmitted infections; WBCs, white blood cells.

Pelvic pain is the most common symptom of PID, although it may be mild in some women. Other symptoms are listed in Box 52.2, although the absence of these findings does not exclude PID. A through history, including an assessment of symptoms, risk factors, sexual and menstrual history, and prior STD, is essential in making an accurate diagnosis. A pelvic examination should be performed to assess for signs of cervical inflammation (i.e., cervicitis), including mucopurulent discharge and cervical friability (i.e., easy bleeding to touch). After the speculum examination and collection of the appropriate microbiologic samples, a bimanual examination should be performed to assess for cervical, uterine, or adnexal tenderness or masses. Microscopy of the vaginal secretions can be performed to evaluate leukorrhea (>1 leukocyte per epithelial cell).

Box 52.2

Symptoms Associated With Clinically Suspected Pelvic Inflammatory Disease

Abdominal pain

Abnormal purulent discharge

Metrorrhagia (i.e., uterine bleeding at irregular intervals)

Postcoital bleeding

Fever

Dysuria

Nausea and vomiting

When there is concern about a tubo-ovarian abscess or the patient is not responding to conventional therapy for PID, further diagnostic evaluation using imaging studies can be helpful. Although other causes of pelvic or abdominal pain should be explored, the rarity of some of these conditions in adolescence helps to narrow the diagnosis (Box 52.3 and Table 52.1). Healthcare personnel should maintain a low threshold for treating PID in at-risk populations (e.g., sexually active adolescents), and empiric therapy should be initiated unless another cause is discovered.

Box 52.3

Differential Diagnosis of Pelvic Inflammatory Disease

Gynecologic Causes

Pregnancy (i.e., ectopic or a septic or threatened abortion)

Ovarian cyst (i.e., intact, ruptured, or torsed)

Endometriosis

Mittelschmerz (i.e., pain associated with ovulation)

Dysmenorrhea

Gastrointestinal Causes

Appendicitis

Constipation

Diarrhea

Gastroenteritis

Inflammatory bowel disease

Irritable bowel syndrome

Urinary Tract Causes

Cystitis

Urethritis

Urinary calculus

Pyelonephritis

Modified from Shrier LA. Bacterial sexually transmitted infections: gonorrhea, chlamydia, pelvic inflammatory disease, and syphilis. In: Emans SJH, Laufer MR, Goldstein DP (eds). Pediatric and Adolescent Gynecology, 5th ed. Philadelphia, Lippincott-Raven, 2005, p. 591.

TABLE 52.1

Characteristics of Pelvic Inflammatory Disease, Ectopic Pregnancy, and Acute Appendicitis

Characteristic	Pelvic Inflammatory Disease	Ectopic Pregnancy	Acute Appendicitis
HISTORY			
Age	Any after puberty	Risk increases with age	Any
Onset of symptoms	75% within 7 days of menses	At 4 weeks' gestation or later; rupture at 6–10 weeks' gestation	Any
Abdominal pain	Dull, crampy, localized to lower abdomen; possible right upper quadrant pain (perihepatitis)	Before rupture: localized or diffuse, dull abdominal pain After rupture: severe, poorly localized pain, rectal pressure	Poorly localized periumbilical or epigastric pain with shift to right lower quadrant after 4–6 hours; increasing severity
Vaginal discharge	55%	Not associated	Not associated
Menstrual pattern	Metrorrhagia; missed menstruation not associated	Intermittent bleeding or spotting; often missed or late menstruation	No change in usual pattern
Fever	>38°C in up to 35%	>38°C in up to 20%	Usually <38°C; >38°C after perforation
Nausea and	Uncommon	Uncommon	50%–60%

vomiting			
SIGNS			
Cervicitis	Purulent exudate in 80%	Not associated	Not associated
Cervical motion tenderness	>95%	Can be elicited; not as pronounced as in salpingitis	Usually none; can occur with perforation if appendix adjacent to adnexa
Adnexal mass	5%–50%	35%–50%	Not associated
LABORATORY EVALUATION			
Anemia	Not associated	Significant (hematocrit <25%) after rupture	Not associated
Leukocyte count	Normal or elevated	Usually elevated	Mildly elevated
Pregnancy test	Usually negative	Positive 1–2 weeks after conception	Usually negative but pregnant patients can have appendicitis
Ultrasonography	Common findings: cul-de-sac fluid, adnexal enlargement, complex adnexal mass	Intrauterine gestational sac absent	Can detect inflamed appendix
Laparoscopy	Inflammation of fallopian tubes	Fallopian tube pregnancy with or without rupture	Normal fallopian tubes; inflamed appendix

Modified from Paradise JE, Grant L. Pelvic inflammatory disease in adolescents. Pediatr Rev 1992;13:216–223.

Laboratory Findings and Diagnosis

A cervical or vaginal nucleic acid amplification test for *C. trachomatis* and *N. gonorrhoeae* should be obtained for all patients with suspected PID.[42] Laboratory confirmation of an STD is helpful but is not necessary to justify initiation of therapy for PID. Treatment should not be delayed if PID is suspected on clinical evaluation. Patients can be assessed for other vaginal infections such as BV and *Trichomonas vaginalis*. Molecular tests for *M. genitalium* are becoming available commercially.

All women diagnosed with acute PID should have a pregnancy test to exclude ectopic pregnancy, and they should be screened for human immunodeficiency virus (HIV) infection.[42] Pregnancy always should be excluded in sexually active women evaluated for pelvic pain.

An elevated white blood cell count discovered by serum testing is a nonspecific marker of PID. An elevated erythrocyte sedimentation rate or C-reactive protein level can increase the specificity, but the clinical usefulness is limited.[43] Although an endometrial biopsy offers an acceptable approach to documenting inflammation of the upper genital tract, a biopsy usually is not performed for adolescents, and the delay between the biopsy and final histopathologic report makes this test most appropriate for cases in which there is diagnostic uncertainty. Although laparoscopy is considered the gold standard for the diagnosis of PID, costs and surgical risks preclude the universal use of laparoscopy for the diagnosis of PID. HIV and syphilis testing should be offered.

Management

The principles of management and criteria for hospitalization are outlined in Box 52.4. The severity of disease usually dictates whether a patient is treated on an outpatient or inpatient basis. Most women with uncomplicated PID are treated on an outpatient basis with oral therapy because long-term outcomes are not improved with parenteral antibiotics.[19]

Box 52.4

Principles of Management of Pelvic Inflammatory Disease

- Exclude pregnancy and appendicitis
- Use minimum criteria to guide diagnosis[a]
- Err on the side of overdiagnosis
- Perform testing for *Chlamydia trachomatis* and *Neisseria gonorrhoeae*
- Consider screening and treating for lower genital tract infections, including bacterial vaginosis and *Trichomonas vaginalis*
- Offer HIV testing to all women diagnosed with acute PID
- Treat early and with broad-spectrum antibiotics
- Reassess patient 48–72 hours after initiating therapy
- Criteria for hospitalization

- Surgical emergency (e.g., appendicitis cannot be excluded)
- Patient is pregnant
- Patient does not respond clinically to oral antimicrobial therapy
- Patient is unable to follow or tolerate an outpatient oral regimen
- Patient has severe illness, nausea and vomiting, or high fever
- Patient has a tubo-ovarian abscess

- Identify, evaluate, and treat sex partners. In settings where only women are treated, male sex partners should be referred for appropriate treatment.
- Educate patient about STI prevention (see Chapter 49), including abstinence, encouraging the use of barrier methods of protection, and regular assessment for STIs

HIV, Human immunodeficiency virus; *PID*, pelvic inflammatory disease; *STI*, sexually transmitted infection.

---

[a] See Box 52.1.

A critical component of outpatient management is short-term follow-up, especially in the adolescent population. Adolescent patients should be reassessed 2 to 3 days after oral antibiotics are prescribed to ensure satisfactory improvement. It is important to consider that adolescents may be reluctant to disclose their diagnosis of PID or have greater dependence on adults for financial and logistical support, and they may not be able to obtain prescriptions or keep follow-up appointments.

PID treatment regimens provide broad-spectrum coverage of likely pathogens. Current guidelines recommend that empiric treatment for PID be initiated in sexually active young women and other women at risk for STDs if they are experiencing pelvic or lower abdominal pain, if no cause for the illness other than PID can be identified, and if cervical motion, uterine, or adnexal tenderness are identified on cervical examination (see Table 52.1).[42] Additional supportive criteria are intended to help clinicians recognize when PID should be suspected and when additional information is needed to increase diagnostic certainty.

Recommended treatment regimens for PID are outlined in Table 52.2. The need to cover anaerobes has not been definitively established, but because BV is commonly found in women with PID, some experts recommend an agent with activity against β-lactamase–producing anaerobes. Increased gonococcal resistance to quinolones has led to the discontinuation of recommending a quinolone agent for the treatment of acute PID. Concerns about compliance and tolerability issues, especially among adolescents, have prompted a search for alternative regimens that demonstrate efficacy equal to currently recommended regimens. Although most patients are successfully treated as outpatients, there is a poor correlation between short-term responses and long-term sequelae such as infertility.[44]

TABLE 52.2

Centers for Disease Control and Prevention Treatment Guidelines for Acute Pelvic Inflammatory Disease

Parenteral Regimens	Oral Regimens
RECOMMENDED REGIMENS	RECOMMENDED REGIMENS
Cefotetan, 2 g IV every 12 hr *Or* Cefoxitin, 2 g IV every 6 hr *Plus* Doxycycline, 100 mg PO or IV every 12 hr. Clindamycin, 900 mg IV every 8 hr *Plus* Gentamicin, loading dose IV or IM (2 mg/kg of body weight) followed by a maintenance dose (1.5 mg/kg) every 8 hr. Single daily dosing (3–5 mg/kg) can be substituted.	Ceftriaxone, 250 mg IM in a single dose *Plus* Doxycycline, 100 mg orally bid for 14 days *With or without* Metronidazole, 500 mg orally bid for 14 days. Cefoxitin, 2 g IM in a single dose, and probenecid, 1 g PO administered concurrently in a

ALTERNATIVE REGIMENS	
Ampicillin-sulbactam, 3 g IV every 6 hr *Plus* Doxycycline, 100 mg PO or IV every 12 hr.	single dose *Plus* Doxycycline, 100 mg PO bid for 14 days *With or without* Metronidazole, 500 mg PO bid day for 14 days. Other parenteral third-generation cephalosporin (e.g., ceftizoxime, cefotaxime) *Plus* Doxycycline, 100 mg PO bid for 14 days *With or without* Metronidazole, 500 mg PO bid for 14 days.

Modified from Workowski KA, Bolan GA; Centers for Disease Control and Prevention. Sexually transmitted diseases treatment guidelines, 2015. MMWR Recomm Rep 2015;64(RR-3):1–137.

Complications and Sequelae

Several factors, including the number of PID episodes, severity of infection, and delayed diagnosis or treatment, can influence a woman's risk of developing adverse reproductive long-term outcomes. At least one fourth of women with PID experience one or more serious sequelae, including increased risk of ectopic pregnancy (6- to 10-fold increased rate), tubal factor infertility, or chronic abdominal pain (3-fold increased rate).[45–47] Women treated within 3 days of the onset of illness have improved fertility compared with women whose treatment is delayed, reinforcing the importance of early and often empiric treatment.

Prevention

Adolescents should be queried about their sexual activity and risk factors, and they should be educated about the symptoms and signs of STD and PID. They should be screened routinely for STDs and offered treatment according to accepted guidelines. The U.S. Preventive Services Task Force recommends annual chlamydia and gonorrhea screening for all sexually active females 24 years of age or younger and for older women at increased risk for infection.[48] There is evidence that screening for and treating *C. trachomatis* reduces the incidence of PID and its sequelae.[49–51] The rate of PID among an asymptomatic study population undergoing risk-based enhanced screening for *C. trachomatis* was reduced by 66% compared with controls.[47]

Because STDs play a major role in PID, diagnosis and treatment of male sexual partners is critical to prevent reinfection and improve the long-term health of young women.[19,39] Repeat testing for gonorrhea or chlamydia in 3 to 6 months is recommended if initial testing is positive for either infection. Unprotected intercourse should be avoided until both partners have completed their course of antibiotics to avoid reinfection. The diagnosis of PID gives healthcare personnel an opportunity to perform counseling about safer sex practices and risk reduction.

Epididymitis, Orchitis, and Prostatitis

Noni E. MacDonald, William R. Bowie

Epididymitis

Epididymitis is an inflammatory reaction or infection of the epididymis, the coiled tubular structure attached to the upper posterior part of each testicle that collects, stores, and matures sperm.

Etiology, Epidemiology, and Pathogenesis

Accurate epidemiologic data on epididymitis are lacking, but this disorder is common in sexually active older adolescents and young adult men; epididymitis is rare in prepubertal boys, however, with a reported incidence of only 1.2 in 1000 boys and peak hospital admissions in summer and winter.[1–3] The age distribution in boys is bimodal, with peaks at <5 years of age and then again in early puberty.[4] Acute epididymitis in boys is more common than testicular torsion.[5,6]

Epididymitis can occur as an inflammatory postinfectious reaction to several bacterial and viral pathogens,[1,3,7] or it can be a complication of urethral infections caused by sexually transmitted pathogens,[1,8] by genitourinary tract pathogens (especially if predisposing obstructive anatomic conditions, neurologic genitourinary abnormalities, or anorectal malformations exist),[6,9–12] or, more rarely, through hematogenous spread to the epididymis from a primary focus of infection (e.g., *Haemophilus influenzae* type b, *Salmonella* spp., *Streptococcus pneumoniae, Brucella* spp. or *Mycobacterium tuberculosis*).[13] The microbial cause and predisposing factors in acute bacterial epididymitis in children and adolescents vary with age (Table 53.1). Occasionally, epididymitis is not caused by inflammation or infection but is related to trauma, systemic diseases (e.g., Henoch-Schönlein purpura or Kawasaki disease), or medications (e.g., amiodarone).[2,3,12,14,15] Recurrent epididymitis in a prepubertal boy suggests an underlying genitourinary disorder.[16]

TABLE 53.1

Microbial Etiology and Predisposing Factors in Acute Epididymitis in Children and Adolescents

Predisposing Factors	Etiology	Incidence
PREPUBERTAL CHILDREN		
Underlying structural or neurologic abnormalities of the genitourinary tract	Enterobacteriaceae *Pseudomonas aeruginosa*	Uncommon
Hematogenous spread from primary focus	*Haemophilus influenzae* type b *Streptococcus pneumoniae* *Neisseria meningitidis* *Salmonella* spp.	Uncommon
Postinfectious factors	Adenovirus, enterovirus *Mycoplasma pneumoniae*	Uncommon
ADOLESCENTS		
Urethritis	*Chlamydia trachomatis*	Related to frequency of sexual activity
	Neisseria gonorrhoeae	
Underlying genitourinary tract disorder	Enterobacteriaceae *Pseudomonas aeruginosa*	Uncommon
Hematogenous spread from primary focus	*Streptococcus pneumoniae* *Neisseria meningitidis* *Mycobacterium tuberculosis*	Rare

Clinical Manifestations and Differential Diagnosis

Epididymitis, whether inflammatory or infectious in origin, typically has an acute onset, with unilateral scrotal pain and swelling that increases over 1 or 2 days. Commonly associated symptoms include dysuria and other lower urinary tract symptoms. Sexually transmitted epididymitis usually is accompanied by urethritis, which frequently is asymptomatic. Differentiation of epididymitis from testicular torsion, which requires immediate surgical intervention, is critical.[17,18] Bacterial orchitis, an extension of epididymitis, is another important consideration in the differential diagnosis, especially in prepubertal children. Table 53.2 compares the clinical and laboratory differences among these disorders. The presence of Prehn sign (i.e., relief of pain with testicular elevation) supports the diagnosis of epididymitis but is not definitive.[19] The cremasteric reflex usually is present in epididymitis but is absent in testicular torsion. The presence of urethral discharge is suggestive but not diagnostic of epididymitis. In prepubertal boys with acute scrotal pain, urinalysis and urine culture frequently are performed; but a positive yield is low in epididymitis.[7,20,21] Ultrasonography, radionuclide scan, and, occasionally, magnetic resonance imaging[13,18–25] are helpful in differentiating among these entities (see Table 53.2). For the diagnosis of acute epididymitis, although radionuclide scan was recommended in the past as most accurate, it is not routinely available, and color duplex Doppler ultrasonography is now more often recommended.[25]

TABLE 53.2

Comparison of Clinical Manifestations and Laboratory Findings in Acute Epididymitis, Acute Orchitis, and Testicular Torsion in Children and Adolescents

		Acute Orchitis		
	Acute Epididymitis	**Bacterial**	**Viral**	**Testicular Torsion**
CLINICAL FEATURES				
Most common age	Adolescence	Rare in childhood	Adolescence	Peripubertal
Predisposing factors	After puberty: urethritis	Epididymitis	Failure to be immunized against	None

	(sexually transmitted infection)		mumps	
	Before puberty: structural abnormality			
PAIN				
Onset	Gradual	Gradual	Acute; occasionally gradual	Acute
Severity	Mild to severe	Moderate to severe	Mild to severe	Severe
Fever	Moderate	Moderate to high	Low to high	Uncommon
SYSTEMIC SYMPTOMS				
Anorexia, vomiting, malaise	Can occur with severe infection, uncommon	Common	Can occur	Uncommon
Dysuria	Common	Common	Can occur	Uncommon
SCROTAL FINDINGS				
Testicular lie	Vertical (normal)	Vertical	Vertical	Possibly horizontal
Swelling	++; usually unilateral	++	++ to +++	+
Prehn sign	Pain ↓	Pain ↓	No change in pain	Pain unchanged or ↓
Cremasteric reflex	Usually present	Usually present	Usually present	Usually absent
Tenderness				
Testes	± epididymis tenderness	++	+ to ++ (can be unilateral)	++
Spermatic cord	++	++	++	−
Presence of hydrocele	Common	Common	−	−
Skin inflammation	++	+	−	± (~30%)
Urethral discharge	Possible	Possible	−	−
LABORATORY FINDINGS				
Peripheral blood leukocytosis	++	++	±	±
C-reactive protein	++	+	++	Normal
Pyuria (>10 WBCs/hpf)	++	±	Usually −	Usually −
IMAGING FINDINGS				
Epididymis				
Doppler blood flow	↑ or normal vascularity	↑ vascularity	↑ vascularity	↓ vascularity or avascular
Sonogram	Enlarged and thickened	↑ perfusion	↑ perfusion	Enlarged with ↑ echotexture versus opposite side
Testis				
Doppler	↑ or normal	↑ vascularity	↑ vascularity	↓ vascularity

blood flow	vascularity			or avascular
Sonogram	Enlarged, hypervascular; ↑ perfusion	Testicular masses or swollen testicles with hypoechoic and hypervascular areas	Testicular masses or swollen testicles with hypoechoic and hypervascular areas	No change in echotexture unless late

+, mild to moderate; ++, moderate to severe; ±, variably present; −, absent; ↑, increased; ↓, decreased; WBCs, white blood cells.

Laboratory Findings and Diagnosis

Organisms responsible for infectious epididymitis usually can be isolated from urine and urethral specimens, especially when a sexually transmitted infection (STI) is suspected. A Gram stain of urethral exudate or an intraurethral swab specimen and a culture of intraurethral exudate or a nucleic acid amplification test (NAAT) (either on an intraurethral swab or first-void urine) for *Chlamydia trachomatis* and *Neisseria gonorrhoeae* are indicated.[1] As with any STI syndrome, testing for other STIs, including human immunodeficiency virus (HIV) infection, should be considered based on the patient's sexual history and risk factors (see Chapter 49). For prepubertal cases, culture of urine is recommended but may not reveal a pathogen.[19,20]

Management and Complications

Early empiric treatment of suspected STI epididymitis cures the infection, improves the symptoms and signs, prevents transmission of these STI microbes to others, and decreases potential complications.[1,26] For epididymitis most likely caused by gonococcal or chlamydial infection, the recommended treatment regimen is ceftriaxone (single 250-mg intramuscular dose) in addition to doxycycline (100 mg orally twice a day for 10 days) while awaiting laboratory test results.[1,26] For acute epididymitis most likely caused by enteric organisms such as *Escherichia coli* or *Pseudomonas,* levofloxacin or ofloxacin is recommended.[26] Bearing in mind the low rate of positive urine culture results in prepubertal boys with epididymitis, antibiotic therapy is reserved for young infants and for boys with pyuria or positive urine culture results.[27] In addition to antimicrobial therapy, bed rest, scrotal elevation, and administration of analgesics are recommended until fever and local inflammation resolve. Failure of symptoms to improve within 3 days requires reevaluation of the diagnosis and therapy, and it can require hospitalization. If an STI is identified, any sexual partners are contacted for assessment and treatment.

Patients with isolated gram-negative organisms also may need investigation for underlying anatomic or neurologic abnormalities that may be causing urinary tract obstruction. Direct aspiration of the epididymis for specimen collection can be done if other testing does not provide the answer or if evidence of an abscess is present.

In patients with inflammatory postinfectious reactive epididymitis, treatment includes analgesics and supportive care; antimicrobial therapy is not indicated.[27] Complications of epididymitis include testicular abscess, chronic epididymitis, testicular infarction, and infertility. Drainage of scrotal abscesses or orchiectomy is seldom needed if the condition is diagnosed and treated promptly and close follow-up is performed.

Orchitis

Orchitis, inflammation of the testis, rarely occurs in prepubertal patients. Although bacterial epididymo-orchitis does occur, usually infection has spread from the epididymis to include the testicle.[28] Primary orchitis is uncommon except with certain viral diseases, especially mumps.[29–31] Less frequently, enterovirus[32] or, rarely, adenovirus,[33] varicella-zoster virus,[34] or West Nile virus[35] is responsible.

When associated with mumps, orchitis usually follows parotitis by 4 to 8 days, but it can develop up to 6 weeks after parotid gland involvement or in the absence of parotitis. The onset of viral orchitis can be gradual but usually is abrupt with mumps[29] and is heralded by fever, chills, nausea, and lower abdominal pain (see Table 53.2). When the right testis is involved, appendicitis can be suspected erroneously if the scrotum has not been examined carefully. The affected testis is warm, swollen and tender, and the adjacent skin is edematous and red. Patients with mumps orchitis appear to have high levels of interleukin-6 and interferon γ but not as high as in acute mumps meningitis or mumps encephalitis.[30] The mumps virus can be detected in the semen for 14 days, and mumps RNA can be detected for up to 40 days.[36] Mumps orchitis is associated with a transient but significant reduction in sperm count and abnormal sperm morphology, which can account for the long-term adverse effect on fertility in some patients.[37] Although antisperm antibodies can be detected, they do not seem to play a role in mumps orchitis or in subsequent infertility.[37]

Bacterial epididymo-orchitis usually occurs as a consequence of contiguous spread from bacterial epididymitis and is caused by organisms such as *E. coli, Pseudomonas aeruginosa,* and *Klebsiella* or from hematogenous seeding from another source such with *Brucella.*[13] Signs and symptoms are similar to those of epididymitis (see Table 53.2).

Management of viral orchitis is supportive and symptomatic, and it consists of bed rest and analgesia. Corticosteroid therapy is not recommended because no evidence indicates that therapy speeds resolution, and corticosteroids may contribute to testicular atrophy.[37] Early treatment of mumps orchitis with interferon α_{2B} can lead to earlier symptom resolution.[38] Bacterial epididymo-orchitis is treated with antimicrobial therapy (see the earlier section on epididymitis). Surgical treatment may be necessary if testicular abscess or pyocele of the scrotum occurs. Infertility can result from viral or bacterial orchitis, but it is uncommon even after bilateral mumps.[27,37]

Prostatitis

Prostatitis, inflammation of the prostate, encompasses a group of poorly defined clinical entities associated with pelvic and genital pain or discomfort and variable voiding and sexual complaints[39,40]

Etiology, Pathogenesis and Epidemiology

The National Institutes of Health consensus classification of prostatitis includes 4 syndrome categories: (1) acute bacterial prostatitis, (2) chronic bacterial prostatitis, (3) chronic prostatitis or chronic pelvic pain syndrome, and (4) asymptomatic inflammatory prostatitis.[41] Prostatitis does not occur in prepubertal boys and is unusual in adolescents and young adults.[40] Suggested risk factors for bacterial prostatitis include urinary tract instrumentation, urethral strictures, and urethritis.[39] Pathogens reach the prostate by reflux of infected urine, hematogenous spread, or lymphatic spread.

The most commonly associated pathogen is *E. coli,* which is found in 65% to 80% of cases; *P. aeruginosa, Klebsiella* spp., *Serratia* spp., and *Enterobacter aerogenes* account for 10% to 15% of cases.[39,40] In adolescents, sexually transmitted pathogens are not a cause of bacterial prostatitis except when prostatitis accompanies Reiter syndrome precipitated by *C. trachomatis.* Reflux of sterile urine, which incites an inflammatory reaction, can contribute to noninfectious prostatitis.

Clinical Manifestations and Differential Diagnosis

Acute bacterial prostatitis typically manifests abruptly, although occasionally insidiously, with voiding symptoms, poorly localized pain, and often fever and malaise. In adolescents, the sudden onset of chills, fever, and malaise with voiding difficulties is much more likely to be caused by urinary tract infection, epididymitis, or urethritis than by acute bacterial prostatitis. With acute bacterial prostatitis, rectal examination usually is painful, and the prostate is warm, tense, and swollen. Prostatic massage is not recommended because this can precipitate bacteremia.

In adolescents, scrotal or pelvic pain variant also is a possibility. These patients have a history of vague scrotal pain with or without voiding symptoms but no fever and, on examination, no objective physical findings. Adults with chronic bacterial prostatitis have symptoms of recurring episodes of pain or discomfort in the perineum, groin, lower back, or scrotum, as well as voiding dysfunction, and they usually have a history of recurrent urinary tract infection. Often, prostatic examination is not helpful because findings are variable.

Nonbacterial (inflammatory) prostatitis and chronic pelvic pain syndrome are also seen in adults with a presentation similar to that of chronic bacterial prostatitis but without the history of preceding urinary tract infection. On examination, the prostate is either boggy, with nodular areas caused by inflammation, or is fibrous and difficult to massage. Whether chronic prostatitis occurs in adolescents is unclear, but 2 studies suggest it does, albeit at a low rate.[42,43]

Laboratory Findings and Diagnosis

When acute bacterial prostatitis is suspected based on clinical findings, urinalysis, urine culture, and STI screening are indicated, as well as blood cultures and a complete blood count.[39] In patients with suspected chronic prostatitis or nonbacterial prostatitis, prostate fluid is cultured and examined for leukocytes. Examination of expressed prostate secretions has been the definitive test for differentiating the prostatitis syndromes since introduction of the prostate localization 4-cup urine collection test.[40] This method is cumbersome, time-consuming, and expensive, however, and it has not been well validated.[37] A study of a simpler 2-cup screening test using urine collected before and after prostatic massage reported accuracy similar to that of the traditional 4-cup test.[44] The specimens are sent for quantitative bacterial culture, and Gram stain of the urinary sediment is performed to examine for leukocytes.

Management

Treatment of bacterial prostatitis can be difficult because of limited penetration and activity of antibiotics in acidic prostatic fluid.[39] Parenteral antibiotics, usually a broad-spectrum β-lactam agent with or without an aminoglycoside, are recommended for acute bacterial prostatitis if the patient is systemically ill; the duration of therapy is 2 to 4 weeks.[39] Therapy for less acute cases includes trimethoprim-sulfamethoxazole, a macrolide, doxycycline, or a fluoroquinolone for 2 weeks. If mechanical obstruction is contributing to the problem, correction is required.

No formal guidelines are available for treatment of nonbacterial chronic prostatitis or chronic pelvic pain syndrome, and no proven therapies exist.[40] Antibiotic therapy is not indicated. A report from China on pubertal chronic prostatitis suggested a role for pelvic floor biofeedback training.[43]

Complications

Abscess of the prostate and stone formation are rare complications of acute bacterial prostatitis.[45]

Infectious Diseases Associated With Child Abuse

Beth Emerson, Kirsten Bechtel

Sexual abuse is the persuasion or coercion of a child to engage in sexually explicit conduct.[1] In 2013, of the 679,000 children in the United States found to be abused or neglected, sexual abuse accounted for 9%.[2] Among child victims of sexual abuse in 2012, 26.3% were 12 to 14 years old, and 33.8% were younger than 9 years of age.[3] Most perpetrators of child sexual abuse are adult male caregivers.[2] Federally mandated reporting laws require that all healthcare workers report cases of suspected sexual abuse to child protective service agencies.[4]

Medical Evaluation

In most cases of sexual abuse, the diagnosis is based on the child's statements; rarely are physical residual present from the abuse.[5–7] The following also can be used to confirm the diagnosis: sexually reactive behaviors; penetrating genital trauma without a history of unintentional genital trauma; presence of seminal products in a child; pregnancy; presence of a sexually transmitted infection (STI) beyond the incubation period of vertical transmission (*Neisseria* *gonorrhoeae, Chlamydia trachomatis, Treponema pallidum, Trichomonas vaginalis*).

The decision to perform screening tests for STIs in pediatric victims of sexual abuse depends on the type of abusive exposure, the regional prevalence of STIs in the adult population, previous consensual sexual activity (in adolescents), and most importantly for prepubertal children, the presence of genital symptoms or an abnormal genital examination. Among children evaluated for abuse, the prevalence of STIs is low, and this can affect the positive predictive value of the tests used.[8] Girardet and colleagues[9] found an overall prevalence of STIs of 8.2% in girls (24.5% of girls with vaginal discharge and 6.3% of those without) and 0% in boys with a history of sexual abuse. The presence of 1 STI in any child or adolescent should prompt an evaluation to exclude other STIs. Beyond the perinatal period, during which vertical transmission can occur, these infections usually are acquired from abusive contact.[10]

Infectious Agents

Neisseria gonorrhoeae and *Chlamydia trachomatis*

The prevalence rates for *N. gonorrhoeae* and *C. trachomatis* range from 0.7 to 3.7% in prepubertal children who have been sexually abused.[9,11–14] Most children with such infections are girls with genital complaints (e.g., vaginal discharge) or with abnormal genital examinations.[9,11,13–15] Therefore, the use of routine screening tests for *N. gonorrhoeae* and *C. trachomatis* in otherwise asymptomatic prepubertal girls after sexual abuse is not recommended.[14,16] Up to 14% of adolescent female victims of sexual abuse have an STI.[12,13] This prevalence is higher than in a nonabused, sexually active, adolescent population.[17]

The use of nucleic acid amplification tests (NAATs) in children and adolescents who have been sexually abused has not been extensively studied. Using NAATs can be beneficial in young children because less biologic sample is required, the specimen is less susceptible to environmental changes, and a urine specimen can be used.[18] However, caveats to using NAATs exist.[18–22] Even with their high sensitivity (97%) and specificity (99%), NAATs may have low positive predictive values in prepubertal children because of the low prevalence of *N. gonorrhoeae* and *C. trachomatis* in this population.[18–22] Falsely positive NAATs in prepubertal children could erroneously lead to a diagnosis of sexual abuse.[20,22] Thus, it is our practice to use cultures for *N. gonorrhoeae* and *C. trachomatis* in this population when feasible. If NAATs are used, specimens from tests with positive results should be maintained for additional confirmatory testing (Fig. 54.1).[9,23–25] No data support the use of NAATs for the diagnosis of extragenital infections.[8]

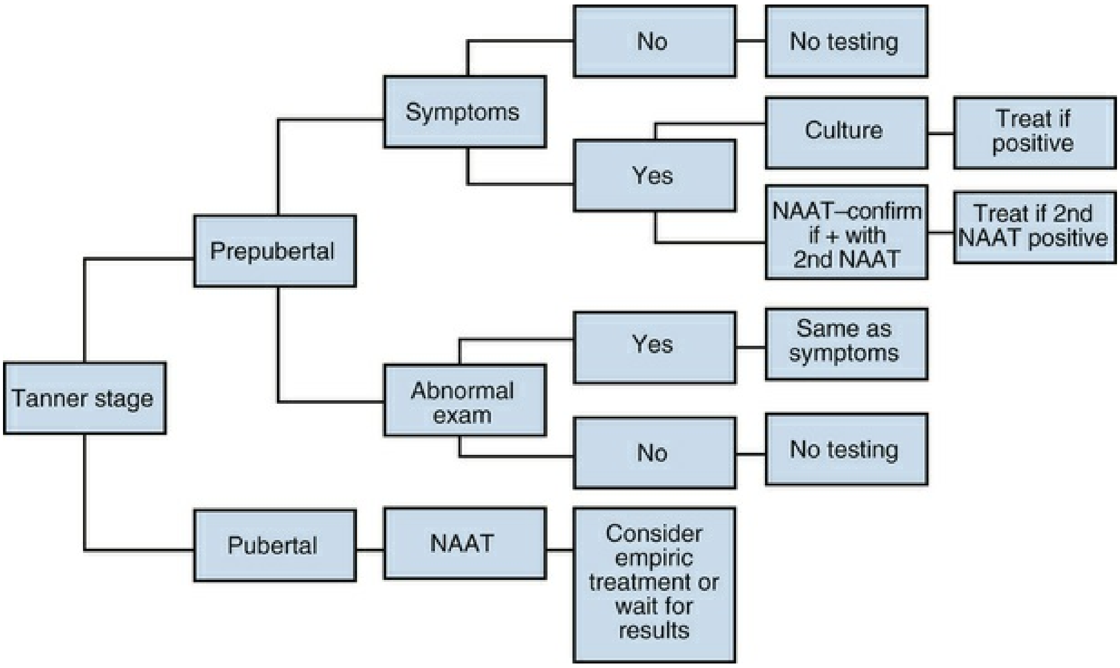

FIGURE 54.1 Algorithm for *Neisseria gonorrhoeae* and *Chlamydia trachomatis* testing in prepubertal and pubertal children. NAAT, nucleic acid amplification test.

Several studies have evaluated NAATs in children who have been sexually abused. Matthews-Greer and colleagues[26] found that polymerase chain reaction (PCR) and culture were equivalent in the detection of *C. trachomatis*. Kellogg and associates[27] found that although agreement among ligase chain reaction (LCR), PCR, and culture for *N. gonorrhoeae* was poor, 84% agreement for urine and vaginal PCR for *C. trachomatis* was noted. These investigators concluded that urine PCR can be substituted for vaginal PCR for the detection of *C. trachomatis* in children and adolescents evaluated for sexual abuse. Neither of these studies confirmed a positive test result by using a second NAAT targeting a different genomic sequence.

Black and colleagues[23] compared urine and genital swabs for *N. gonorrhoeae* and *C. trachomatis* by using PCR confirmed by a second PCR test using an alternate target. The sensitivity of urine NAATs relative to vaginal culture was 100% and resulted in a 33% increase in detection of infection. These results suggest that NAATs performed on urine, with confirmation, may replace culture diagnosis of *N. gonorrhoeae* and *C. trachomatis* in children who have been sexually abused.

Empiric antibiotic treatment for *N. gonorrhoeae* or *C. trachomatis* generally is not indicated for asymptomatic prepubertal girls who have been sexually abused.[28–33] If NAATs are used, any positive test result should be confirmed by a culture or a second NAAT that targets a different genomic sequence.[24] Empiric antibiotics should be prescribed only if the confirmatory test result is positive. One could consider empirically treating sexually abused adolescents after cultures or NAATs have been obtained because the prevalence of infection is higher and false-positive test results are less common.

Azithromycin and doxycycline are the antibiotics of choice for adolescents warranting postexposure prophylaxis (PEP) against *C. trachomatis*. Ceftriaxone or cefixime are indicated for prophylaxis against *N. gonorrhoeae*.[25,34]

Treponema pallidum

Syphilis is an uncommon infectious complication of child abuse.[35,36] Girardet and colleagues[9] found a prevalence of 0.3% among children referred for evaluation after sexual abuse. Sexual transmission should be assumed in children who contract syphilis.[37] Determining the mode of acquisition of syphilis in preverbal children can be difficult. Horowitz and Chadwick[35] and Christian and associates[38] described 5 such children who presented with signs of secondary syphilis, including condylomata lata (3 children), syphilitic nephropathy (1 child), and corymbiform rash (1 child). The child with syphilitic nephropathy had a history of genital rashes consistent with a primary chancre and condylomata lata that were missed by medical providers.[30] None of these cases had a history from the child or caregivers of sexual abuse. When the mode of transmission of an STI is likely to be sexual abuse, a comprehensive investigation is needed to ensure that the child has no other STI and that no other children in the home have a history of sexual abuse or an STI.[35,38]

Human Papillomavirus

The most common human papillomavirus (HPV) subtypes that cause genital warts are 6, 11, 16, and 18. Although the methods by which children acquire genital warts are unclear, sexual abuse is the most worrisome form of transmission.[39] Vertical acquisition at delivery may not become clinically apparent for years and may not be the sole source of nonabusive HPV infection in infants and young children. Horizontal mother-to-child transmission can occur during childhood. Marais and colleagues[40] evaluated the likelihood of vertical maternal-to-child transmission by measuring serum antibodies to HPV-16 and HPV-18. The prevalence of antibodies was higher in children of seropositive mothers compared with seronegative mothers, but these differences were not statistically significant. Castellsague and associates[41] found that at a mean age of 14 months, 19.7% of infants born to mothers with cervical HPV and 16.9% of infants born to HPV-negative mothers tested positive for HPV. Dunne and colleagues[42] evaluated the prevalence of antibodies to HPV-16 in a sample of children 6 to 11 years of age. Overall, 2.4% of 1316 children were seropositive. Seroprevalence was higher in boys than in girls (3.5% vs. 1.2%), and in children >7 years of age than in younger children (3.3% vs. 0.4%). Unger and associates[43] reported an association of HPV positivity with sexual abuse in a sample of patients aged 6 months to 13 years.

Several investigators have evaluated the mode of acquisition of genital warts in children. Marcoux and colleagues[44] concluded that the modes of acquisition in children cannot be identified either by the clinical appearance of the lesions or by HPV typing. Sinclair and associates[45] evaluated the likelihood of sexual abuse in 55 children with HPV anogenital infection; 31% of the children provided a history of sexual abuse. The risk of sexual abuse increased with the child's age at presentation with genital warts (odds ratio of 12.1 in children 8 years of age and older). The positive predictive value of HPV for possible sexual abuse was 36% for children 4 to 8 years of age at diagnosis and 70% for children >8 years of age. No differences were noted in history of parental genital or hand warts in HPV-infected children with and without a history of sexual abuse. An evaluation for sexual abuse is recommended for patients with anogenital warts outside the age range at which exposure during caretaking activities is expected.[46]

Herpes Simplex Virus

Infection with herpes simplex virus (HSV) in children can indicate sexual abuse. This infection also it can result from nonabusive hand-to-genital contact (autoinoculation in a child with primary oral HSV or transmission from caregivers during bathing and toileting).[25] The potential value of typing HSV to determine whether sexual abuse was the mode of transmission is limited by the knowledge that an increasing proportion of genital HSV infections in adults are caused by HSV-1.[47] The prevalence of antibodies to HSV-2 in children and adolescents who have a history of sexual abuse is low, and thus routine screening for HSV-2 antibodies is not useful.[48]

It is more helpful to conduct a careful clinical history in children with genital HSV to determine whether sexual abuse has occurred. A review of several case series in children found that more than one half of reported cases of genital HSV had a sexual mode of transmission; this was reported more commonly in children ≥5 years of age, children with genital lesions only, and those whose infection was caused by HSV-2.[49] A careful assessment for sexual abuse should be performed in any child with genital HSV.

Human Immunodeficiency Virus

Human immunodeficiency virus (HIV) seroconversion after sexual abuse is rare. Gellert and associates[50] found that only 28 (0.4%) of 5622 children who had been sexually abused were HIV seropositive. The mean age of children at the time of diagnosis was 9 years, and 75% provided a clear history of sexual abuse, with 50% describing genital-genital contact. Of the perpetrators, 67% were HIV seropositive, 42% were a parent, 25% were a relative, and 33% had another STI at the time of the child's evaluation.[50] Girardet and colleagues[51] found that of 1750 children screened for HIV at the time of evaluation for sexual abuse, only 1 patient (0.06%) contracted HIV after the abusive contact. In children who have been sexually abused, HIV testing and PEP should be considered in those with a concurrent STI or with mucosal injury resulting in bleeding, those with a perpetrator who either is HIV positive or has high risk for HIV seropositivity, those living in an area with high regional disease prevalence in adults, those whose sexual abuse involved multiple perpetrators, and adolescents with a history of sexual assault by an unknown perpetrator.[52,53]

The rationale for HIV PEP is the possibility of a window during which the viral load can be controlled by the immune system; the commencement of antiretroviral agents during this window potentially would end viral replication. HIV PEP ideally should be initiated within 72 hours of exposure; within 1 hour is optimal.[54] Within this time frame, PEP would be beneficial for children who have been sexually abused.[55] PEP should be given only to patients without a suspicion of current HIV infection, when they and their guardians clearly understand the risks and benefits of PEP and agree to adhere to a follow-up program including serologic testing.[56] However, given that many cases of child and adolescent sexual abuse come to attention after 72 hours, PEP usually is not indicated.

Even if a child or adolescent presents at a time when PEP may be beneficial, no consensus exists on the number or type of antiretroviral agents that should be used. Some investigators recommend 3 drugs only with exposures most likely to transmit HIV infection and to use zidovudine-lamivudine as the base regimen,[57] whereas other investigators suggest that it is important to consider local resistance patterns and to consider a regimen containing zidovudine or stavudine.[58] Centers for Disease Control and Prevention guidelines, as of 2005, for prophylaxis include both non-nucleoside reverse transcriptase inhibitor–based and protease inhibitor–based options.[53] PEP efficacy after sexual exposure has not been evaluated formally. Reports documenting seroconversion after PEP in adults suggest that PEP may not be completely effective, perhaps because of ongoing exposure.[59]

Even when children are provided PEP, often drugs are not administered in a timely fashion or the drugs provided are not appropriate.[54] Other difficulties are compliance and follow-up.[60–63] Even with outpatient support teams and provision of the full course, very few adolescents finish their entire course of PEP drugs.[52,53] Uncertainty about exposure, low follow-up rates, intolerance of side effects, and psychiatric comorbidity also can limit adherence.[60,62]

Trichomonas vaginalis

Trichomonas infection can indicate sexual assault among pediatric patients, but in children younger than 1 year of age, this infection can represent vertical transmission.[64] Among pediatric victims of sexual assault, it is estimated that *Trichomonas vaginalis* infects 4% to 5.9%.[9,65] Between 42% and 90% of these patients can be asymptomatic.[65,66] Several options for testing exist, including wet mount, culture, and NAAT. The sensitivity of wet mount ranges from 36% to 70%; the sensitivity of culture is 81% to 95%.[65–68] The use of NAAT testing and nested PCR analysis has not been approved for prepubertal patients.[8,24,69] Testing of urine samples collected by bag is discouraged because contamination with the gastrointestinal organism *Pentatrichomonas hominis* can cause false-positive results.[8] A single dose of metronidazole is effective treatment.[66]

Vaccine-Preventable Diseases

Sexual assault can include exposures to certain vaccine-preventable diseases. Hepatitis B vaccine should be administered to patients who have not been completely immunized, especially if the patient had genital injuries that resulted in bleeding.[52,53,70] Tetanus booster should be administered if the patient has not received a dose within 5 years and lacerations or abrasions are present.[71]

Gastrointestinal Tract Infections and Intoxications

OUTLINE

55 Approach to the Diagnosis and Management of Gastrointestinal Tract Infections

56 Viral Gastroenteritis

57 Inflammatory Enteritis

58 Necrotizing Enterocolitis

59 Enteric Diseases Transmitted Through Food, Water, and Zoonotic Exposures

55

Approach to the Diagnosis and Management of Gastrointestinal Tract Infections

Jumi Yi, Andi L. Shane

Most infections of the gastrointestinal tract manifest as diarrhea, a clinical syndrome of diverse origin associated with frequent loose or watery stools often accompanied by emesis, fever, abdominal bloating or pain, and occasional extraintestinal manifestations. Infectious diarrhea can have a bacterial, viral, or parasitic origin (Table 55.1), and most cases are associated with specific epidemiologic factors or clinical manifestations.[1] Establishing an etiologic diagnosis for a specific episode sometimes is difficult because of the wide array and complexity of potential agents. Therapy is directed at fluid and electrolyte replacement and maintenance, nutrition, and specific antimicrobial therapy in some cases. The mainstay of prevention is hand hygiene; licensed vaccines are available in the United States for the prevention of typhoid and rotavirus infections.[2,3]

TABLE 55.1

Causative Agents of Gastroenteritis

Bacteria	Parasites	Viruses
Aeromonas species *Bacillus cereus* *Campylobacter jejuni* *Clostridium difficile* *Clostridium perfringens* *Escherichia coli* *Listeria monocytogenes* *Plesiomonas shigelloides* *Salmonella* species *Shigella* species *Staphylococcus aureus* *Vibrio cholerae* *Vibrio parahaemolyticus* *Vibrio vulnificus* *Yersinia enterocolitica*	*Cryptosporidium parvum* *Cyclospora cayetanensis* *Entamoeba histolytica* *Giardia intestinalis* *Cystoisospora belli* Microsporidia (including *Enterocytozoon bieneusi* and *Encephalitozoon intestinalis*)	Astrovirus Enteric adenovirus Norovirus Rotavirus Sapovirus

Epidemiology

Enteropathogens are acquired through the fecal-oral route from person-to-person contact or via contaminated food or water. People with certain host defects may be more susceptible to infection with various enteric pathogens and may experience greater mortality or morbidity.

According to a 2011 estimate, approximately 179 million cases of acute gastroenteritis, defined as acute vomiting or diarrhea, result in 475,000 hospitalizations and 5000 deaths annually in the US.[4] Children at higher risk of death from diarrhea include young infants who were born prematurely, infants residing in crowded settings where dehydration may not be recognized, infants born to mothers who have had little or no prenatal care, and children with underlying immunodeficiencies. In the US, the incidence of diarrhea in children <3 years of age is estimated to be 1 to 3 episodes per child per year, with higher rates in children attending group childcare. Worldwide, diarrheal diseases are leading causes of pediatric morbidity and mortality, with 1.5 billion episodes and 1.5 to 2.5 million deaths estimated annually among children <5 years of age.[5–7] Repeated early-childhood enteric infections can result in long-term disability, including stunted growth.

Most episodes of severe diarrhea worldwide in children <5 years of age are attributed to rotavirus infections[7]; however, hospitalizations attributed to rotavirus infections decreased 60% to 94% in the US since licensure of 2 rotavirus vaccines.[8–11] In 2009, the World Health Organization (WHO) recommended inclusion of a rotavirus vaccine series in all national immunization programs to lower the global disease burden of rotavirus.[5,6,12,13]

Pathogenesis

The gastrointestinal tract is barraged constantly by foreign material, including bacteria, viruses, parasites, and toxins. Numerous protective host factors include gastric acidity, intestinal motility, enteric microflora, glycoconjugates, and specific immune components (cells and humoral compounds). Host age, personal hygiene, intestinal receptors, past exposures, and food intake influence these protective factors and are major determinants of colonization and disease.

The effect of microbial factors is influenced by the size of the inoculum and specific virulence traits of the enteropathogen. For example, *Escherichia coli* can cause gastrointestinal tract disease through the transmission of plasmids or phages that encode for virulence traits, by producing secretory heat-stable or heat-labile enterotoxins and cytotoxins, by promoting invasiveness, or by increasing aggregability. In addition, some bacteria (e.g., *Clostridium botulinum, Staphylococcus aureus,* and *Bacillus cereus*) produce neurotoxins, whereas other bacteria have variations in toxin genes that enhance virulence. Generally, all bacteria that cause gastrointestinal tract disease possess one or more of these virulence traits.

Enteric viruses can cause diarrhea through selective destruction of absorptive cells (villus tip cells) in the mucosa, thus leaving secretory cells (crypt cells) intact, affecting absorptive fluid balance, and also reducing brush-border digestive enzymes.[2,14] *E. coli* pathotypes and many parasitic infections induce similar changes.[14–17]

Clinical Manifestations

Clinical manifestations usually consist of primary gastrointestinal tract manifestations including diarrhea, vomiting, and extraintestinal complications. The WHO defines diarrhea as 3 or more loose or liquid stools per 24 hours, or more frequently than is normal for an individual person. Stools that are formed, regardless of the frequency, or loose, "pasty" stools in infants are not considered diarrheal. Diarrhea can be classified by exposure and by the duration of symptoms, which may provide clues to the implicated pathogen (Fig. 55.1). Clinical manifestations localized to the gastrointestinal tract can be categorized by likely organisms and their pathogenesis for diagnostic and therapeutic considerations (Fig. 55.2 and Table 55.2).

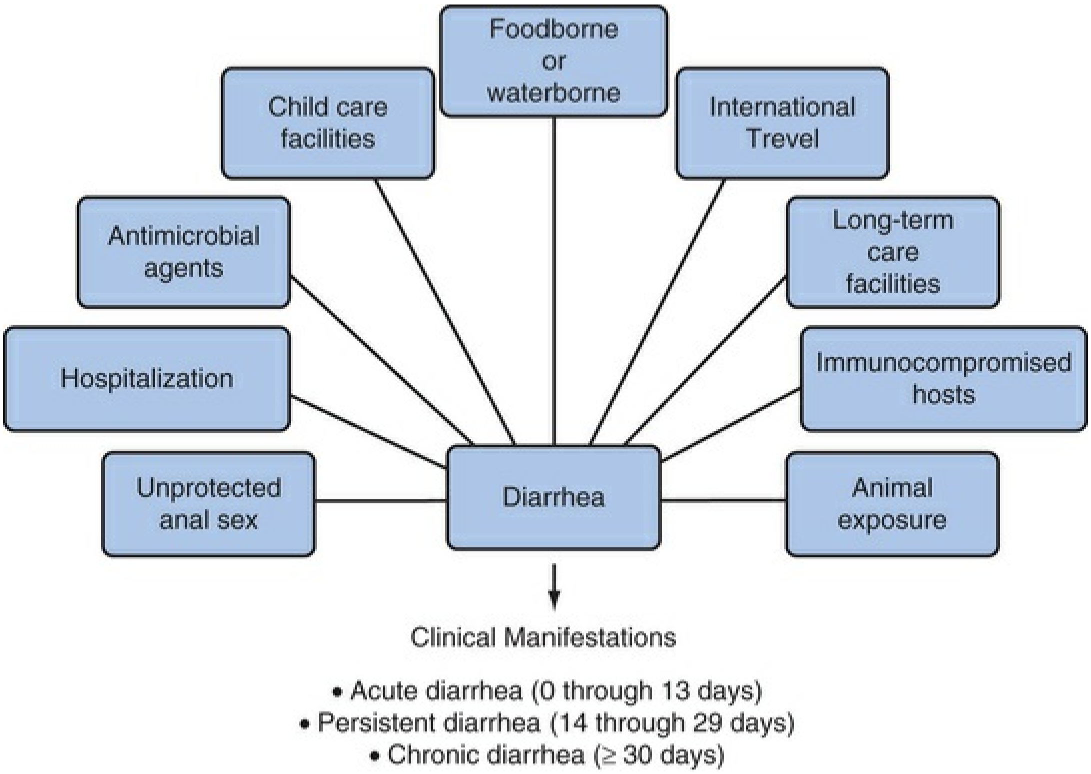

FIGURE 55.1 **Exposures to consider when evaluating people with possible infectious diarrhea.**

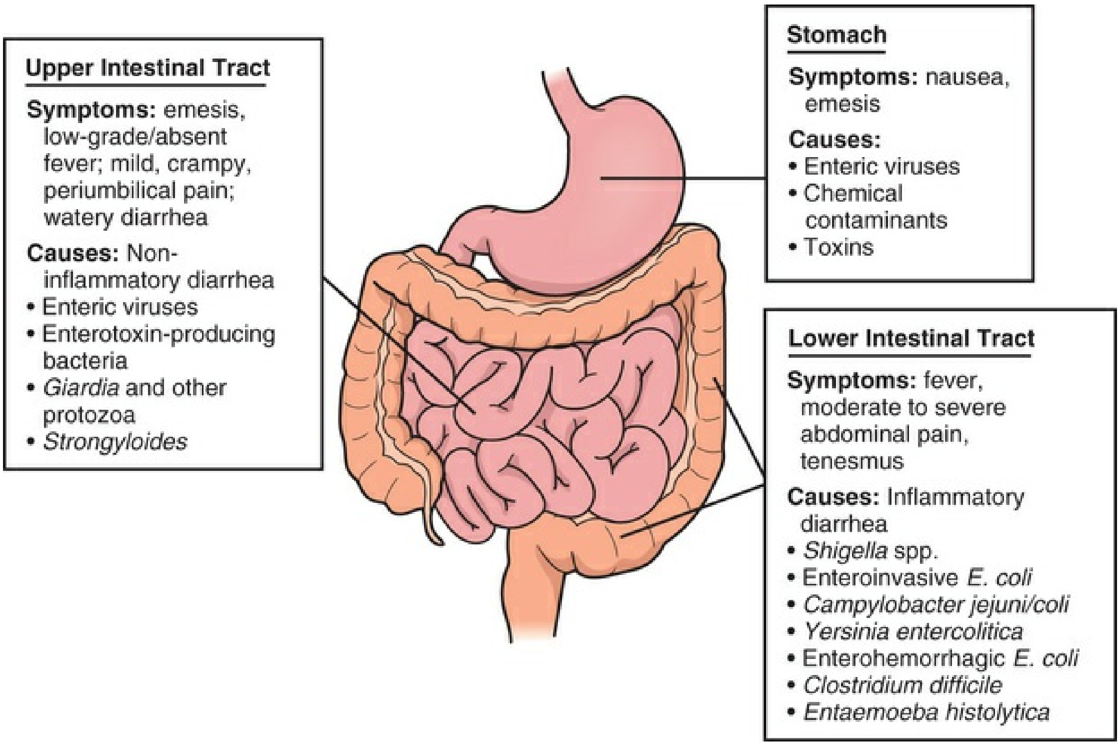

Upper Intestinal Tract

Symptoms: emesis, low-grade/absent fever; mild, crampy, periumbilical pain; watery diarrhea

Causes: Non-inflammatory diarrhea

- Enteric viruses
- Enterotoxin-producing bacteria
- *Giardia* and other protozoa
- *Strongyloides*

Stomach

Symptoms: nausea, emesis

Causes:

- Enteric viruses
- Chemical contaminants
- Toxins

Lower Intestinal Tract

Symptoms: fever, moderate to severe abdominal pain, tenesmus

Causes: Inflammatory diarrhea

- *Shigella* spp.
- Enteroinvasive *E. coli*
- *Campylobacter jejuni/coli*
- *Yersinia entercolitica*
- Enterohemorrhagic *E. coli*
- *Clostridium difficile*
- *Entaemoeba histolytica*

FIGURE 55.2 Localizing gastrointestinal tract signs and symptoms and possible causes of illness.

TABLE 55.2
Clinical Manifestations of Diarrhea and Corresponding Pathogens

Clinical Manifestations	Corresponding Pathogens
Watery diarrhea	Enteric viruses, enterotoxin-producing bacteria, and protozoa that infect the small intestine
Dysentery with scant stools that contain blood and mucus	Pathogens that invade the large intestine such as *Shigella* and *Campylobacter*
Persistent diarrhea that lasts for ≤14 days	Select viruses and bacteria, *Cryptosporidium* spp., *Giardia intestinalis, Cyclospora* spp., *Cystoisospora belli*
Vomiting with minimal or no diarrhea	Chemical contaminants and toxins associated with foodborne and waterborne outbreaks, viral enteropathogens
Bloody stool	STEC, *Shigella* spp., *Salmonella* spp., *Campylobacter* spp., *Entamoeba histolytica,* noncholera *Vibrio* species, *Clostridium difficile*
Abdominal pain	STEC, *Salmonella* spp., *Shigella* spp., *Campylobacter* spp., *Yersinia* spp., noncholera *Vibrio* species, *Clostridium difficile*
Persistent abdominal pain and fever	*Yersinia enterocolitica* (can mimic appendicitis)
Severe abdominal pain, grossly bloody stool (occasionally nonbloody), minimal or no fever	STEC
Nausea and vomiting lasting ≤24 hr	Food poisoning from *Staphylococcus aureus* enterotoxin or *Bacillus cereus*
Diarrhea and abdominal cramping lasting 1–2 days	Food poisoning from *Clostridium perfringens* or *Bacillus cereus*
Vomiting and diarrhea lasting 2–3 days	Norovirus

Chronic, watery diarrhea, often lasting ≤1 yr	Diarrhea of unidentified origin (Brainerd diarrhea), postinfectious irritable bowel syndrome

STEC, Shiga toxin–producing *Escherichia coli.*

Extraintestinal manifestations result from spread of the enteropathogen and immune-mediated mechanisms (Table 55.3), and they usually occur after diarrhea has resolved. In a population-based cohort study, an increased risk of inflammatory bowel disease was demonstrated in people with a preceding episode of gastroenteritis caused by *Salmonella* or *Campylobacter* spp.[18] Functional gastrointestinal disorder, which is defined as the presence of chronic or recurrent gastrointestinal symptoms without a clear cause, may occur in 50% of children with acute gastroenteritis for up to 6 months after the initial infection.[19] This disorder is not well understood but may be explained by multiple etiologic factors including ongoing intestinal inflammation, altered motility, increased intestinal permeability, smooth muscle hyperreactivity, genetic disposition, continuous antigenic exposure, or molecular mimicry.[19]

TABLE 55.3

Extraintestinal Manifestations of Enteric Pathogens

Manifestation	Related Enteric Pathogens
Erythema nodosum[a]	*Yersinia* spp., *Campylobacter* spp., *Salmonella* spp.
Glomerulonephritis[a]	*Shigella* spp., *Campylobacter* spp., *Yersinia* spp.
Guillain-Barré syndrome[a]	*Campylobacter* spp.
Hemolytic anemia[a]	*Campylobacter* spp., *Yersinia* spp.
Hemolytic uremic syndrome[a]	STEC
Immunoglobulin A nephropathy[a]	*Campylobacter* spp.
Reactive arthritis[a]	*Salmonella* spp., *Shigella* spp., *Yersinia* spp., *Campylobacter* spp., *Cryptosporidium* spp.
Reiter syndrome[a]	*Shigella* spp., *Salmonella* spp., *Campylobacter* spp., *Yersinia* spp.
Postinfectious irritable bowel syndrome	*Campylobacter* spp., *Salmonella* spp., *Shigella* spp., STEC, *Giardia intestinalis*
Meningitis	*Listeria monocytogenes, Salmonella* spp. (infants ≤3 mo at high risk)
Intestinal perforation	*Salmonella* spp. (including Typhi), *Shigella* spp., *Campylobacter* spp., *Yersinia* spp.
Encephalopathy, seizure	*Shigella* spp.
Toxic megacolon	*Shigella* spp., *Clostridium difficile*
Aortitis, osteomyelitis	*Salmonella* spp.

[a] Immune-mediated extraintestinal manifestations.

STEC, Shiga toxin–producing *Escherichia coli.*

Considerations of The Host and Exposures

Consideration of possible exposures assists in evaluation of the cause of diarrhea. Etiologic factors may overlap, but specific agents are responsible for most episodes of gastroenteritis following an exposure. Evidence-based recommendations, reviews, and meta-analyses that provide guidance for management of people with diarrhea are available and include information about the following: (1) administration of fluid and electrolyte solutions, (2) clinical and epidemiologic evaluation in immunocompetent and immunocompromised hosts, (3) selection of diagnostic tests, (4) use and avoidance of antimotility agents; (5) institution of selective antimicrobial therapy, (6) immunization recommendations, and (7) prevention of traveler's diarrhea.[1–3,20–27]

Foodborne and Waterborne Disease

Foodborne and waterborne diseases, including infections and intoxications, are acquired by consumption of contaminated food[23–33] at a variety of locations including at home and in restaurants.[34] Major causes of foodborne disease are listed in Table 55.4 (see also Chapter 59). Viruses are the most common causes of foodborne illness, of which 42% to 60% of cases are attributed to norovirus.[23,24,35,36] From 1971 to 2006, cryptosporidiosis was the most common gastrointestinal tract illness reported to the US Waterborne Disease and Outbreak Surveillance System (WBDOSS, http://www.cdc.gov/healthywater/surveillance/).[25]

TABLE 55.4

Causes of Foodborne Illness

Category	Cause
Chemical contaminants	Heavy metals, organic compounds
Bacteria	*Salmonella* spp., *Shigella* spp., *Escherichia coli*, *Brucella* spp., *Yersinia* spp., *Campylobacter* spp., *Vibrio* spp., and *Listeria monocytogenes*
Bacterial toxins	Enterotoxins of *Bacillus cereus*, *Staphylococcus aureus*, *Clostridium perfringens*, *Clostridium botulinum*, *Escherichia coli*
Viruses	Norovirus, rotavirus, and hepatitis A virus
Parasites	*Giardia intestinalis*, *Cyclospora cayetanensis*, *Cryptosporidium* spp., *Taenia* spp., *Toxoplasma gondii*, and *Trichinella* spp.

Products accumulated in the food chain of fish and shellfish	Scombroid, ciguatera, mycotoxins, neurotoxic and paralytic shellfish poisoning, pufferfish tetrodotoxin, domoic acid

An outbreak of foodborne disease is defined as the occurrence in ≥2 people of a similar illness, usually involving the gastrointestinal tract, following consumption of a common food.[23,24] Prompt and thorough laboratory evaluation of involved people and implicated food or water is critical for a definitive diagnosis. Individual cases may be difficult to identify unless a distinct clinical syndrome exists, such as occurs with foodborne botulism.

Most foodborne infections are self-limited and require only supportive care. Exceptions include foodborne and infant botulism (that results in constipation rather than diarrhea), paralytic shellfish poisoning, long-acting mushroom poisoning, and typhoid fever, all of which can result in significant morbidity and death in previously healthy people. Antitoxins or antibiotics may be indicated in the management of these infections, and prevention and control of these diseases are based on avoidance of food contamination or on destruction or denaturation and prevention of further spread or multiplication of contaminants. A suspected case of foodborne illness should be reported to public health officials because it could represent the sentinel case of a widespread outbreak. Detailed information on food safety issues and practices, including steps consumers can take to protect themselves, can be obtained online at the following sites: http://www.foodsafetyworkinggroup.gov, www.foodsafety.gov, www.fightbac.org, and http://www.cdc.gov/foodsafety/outbreaks/index.html. A list of nationally notifiable enteric diseases can be found at http://www.cdc.gov/foodborneburden/surveillance-systems.html.

Waterborne outbreaks occur in the US despite improvements in water management and sanitation. From 2009 to 2010, 33 outbreaks associated with drinking water were reported to the WBDOSS. *Legionella* was most commonly reported, but *Campylobacter* was associated with 12% of the outbreaks resulting in 78% of 1040 illnesses.[37] Recreational water-associated outbreaks may occur through fecal or soil contamination of treated water (e.g., pools and hot tubs) or untreated water (e.g., oceans and lakes) and most commonly manifest as diarrhea. From 2009 to 2010, 27 (33%) of 81 outbreaks were attributed to *Cryptosporidium*, and 24 (30%) were associated with treated recreational water. Enteric bacteria and viruses (*Campylobacter jejuni, E. coli* O157:H7, *Shigella sonnei*, norovirus) were associated with 8 (10%) outbreaks.[38] In addition to maintaining appropriate chlorine and disinfectant levels in pools and hot tubs, the Centers for Disease Control and Prevention (CDC) recommend showering before swimming, checking children with diapers every hour, and taking regular bathroom breaks to prevent contamination of water.[39] Resources for prevention of recreational water illnesses can be found at http://www.cdc.gov/healthywater/swimming/protection/steps-healthy-swimming.html. Recommendations for responding to fecal accidents in swimming venues can be found at http://www.cdc.gov/healthywater/swimming/pdf/fecal-incident-response-guidelines.pdf.

Antimicrobial-Associated Diarrhea

Antimicrobial-associated diarrhea occurs commonly in children and can result from changes in small bowel peristalsis or from alterations in the intestinal microflora. A subset of antimicrobial-associated diarrhea has been associated with *Clostridium difficile* overgrowth and toxin production.[40,41] Risk factors for pediatric *C. difficile* infection include antibiotic exposure within the past 4 to 12 weeks, previous or prolonged (>3 days) hospitalization, and an underlying diagnosis of cancer or inflammatory bowel disease.[41] The increasing trend is toward *C. difficile* detection in hospitalized children,[42–45] but interpretation of the role of *C. difficile* toxin and detection by molecular methods in young children is difficult. Studies have shown that *C. difficile* toxin detection rates are similar in children with and without diarrhea in both the inpatient and outpatient settings.[46–51] Furthermore, *C. difficile* toxin has been isolated in one fourth to two thirds of asymptomatic infants <1 year of age,[46,52] as well as in pediatric gastrointestinal pathology specimens that did not show evidence of the organism on tissue immunohistochemistry or polymerase chain reaction (PCR).[53] Other causes such as concomitant infection, dysbiosis resulting from antibiotics, or alteration in gastrointestinal flora as a consequence of enteral nutrition should be considered as contributing factors when *C. difficile* toxin production is detected.[54]

The American Academy of Pediatrics recommends against testing for *C. difficile* in children <1 year of age (unless they have a severe dysmotility syndrome or in an outbreak situation), recommends considering other causes (especially viral) before *C. difficile* testing, and recommends testing children >3 years of age judiciously. Children who are taking proton pump inhibitors or who have underlying bowel disease, renal insufficiency, or impaired humoral immunity are at greater risk for a *C. difficile* infection.[55] Discontinuation of antibiotics is the first step in the management of a *C. difficile* infection. Metronidazole or vancomycin can be used in children with moderate and severe disease.[55] Diagnostic tests are unlikely to be beneficial in an asymptomatic child unless the child has ileus. Complications of pediatric *C. difficile* infection are rare, and rates of colectomy and morbidity have not increased in affected children as they have among adults.[41,44] The Society for Healthcare Epidemiology of America and the Infectious Diseases Society of America have published clinical practice guidelines for the management of *C. difficile* infections.[56]

Healthcare-Associated Diarrhea

Diarrhea can develop in children as a result of infections acquired before or during healthcare encounters. Episodes that meet the CDC National Healthcare Safety Network definition of a gastrointestinal infection with respect to clinical presentation and timing are considered to be healthcare-associated infections.

Several important factors affect transmission of enteric organisms in hospitals: (1) patient-to-patient transmission through the hands of hospital personnel, generally after contact with a child who has diarrhea; (2) asymptomatic carriers; (3) hospital personnel with gastroenteritis; (4) contaminated food, medications, or medical instruments; (5) hospital crowding; and (6) improper cleaning procedures. Host risk factors include immunocompromised states, prolonged hospitalization, young age, and antibiotic use. Prevention of healthcare-associated gastrointestinal tract infection is best accomplished by prevention and control. Contact isolation is recommended for children with diarrhea or vomiting to prevent transmission of infectious organisms among staff members and children.[57,58] Guidelines for isolation precautions in healthcare settings are available at http://www.cdc.gov/HAI/surveillance/index.html.

Diarrhea in Immunosuppressed Children

Diarrhea may be a presenting symptom of primary immunodeficiency (common variable immunodeficiency, X-linked agammaglobulinemia, and hyper–immunoglobulin M [hyper-IgM] syndrome) or secondary immunodeficiency (human immunodeficiency virus [HIV] infection), it may be a result of transplantation or immunosuppressive drugs, or it may have infectious causes.[59,60] Both enteropathogens of healthy hosts and enteropathogens unique to immunosuppressed children may be implicated. Clinical manifestations and ease of eradication depend on the location of involvement in the gastrointestinal tract, the immune status of the host, the severity of intestinal tract injury, and the availability and effectiveness of therapy. Guidelines have been published for prevention of opportunistic infections, including gastrointestinal tract infections, in HIV-infected people and recipients of hematopoietic stem cell transplants.[61,62]

Gastrointestinal tract disease in children with HIV stage 3, or acquired immunodeficiency syndrome (AIDS), can be caused by enteric infection (e.g., chronic cryptosporidiosis or cystoisosporiasis), malignant disease, wasting syndrome, or invasion by HIV.[62] Organisms and diseases of the gastrointestinal tract that fulfill the surveillance case definition of HIV stage 3 (AIDS) have been published.[63] Before the use of highly active antiretroviral therapy, both acute and persistent episodes of diarrhea and death from opportunistic gastrointestinal pathogens were frequent among HIV-infected infants. The overall incidence of opportunistic infections (including cryptosporidiosis) declined from 14.4 cases per 100 patient-years before the introduction of highly active antiretroviral therapy to 1.1 cases per 100 patient-years after the use of this therapy.[64]

Diarrhea in patients who have undergone allogeneic hematopoietic stem cell transplantation is most commonly caused by to graft-versus-host disease, whereas diarrhea in solid-organ transplant recipients most commonly is the result of infections and immunosuppressive drugs. The most common cause of infectious diarrhea after hematopoietic stem cell transplantation is *C. difficile* infection, and after solid-organ transplantation it is cytomegalovirus, followed by *C. difficile* infection.[59] Gastrointestinal cytomegalovirus infection also occurs in patients with HIV and those with immunosuppression secondary to medications including corticosteroids, chemotherapy, and immunomodulators. Certain immunodeficiencies increase the risk of infection with specific enteropathogens. For example, patients with selective IgA deficiency and common variable immunodeficiency are at increased risk for infection with *Giardia intestinalis*, and patients with hyper-IgM are at increased risk for infections with *Cryptosporidium* species.[60]

Diarrhea in Out-of-Home Childcare Settings

The greater use of out-of-home childcare has had a significant impact on the epidemiology of diarrheal disease in the US (see Chapter 3). After respiratory tract illness, diarrhea is the most common disease among children in childcare facilities, and it occurs at a rate of approximately 3 cases per year among children <3 years of age.[65] Norovirus, rotavirus, enteric adenoviruses, astroviruses, *Shigella* species, *Cryptosporidium* species, *E. coli* O157:H7, and *G. intestinalis* are the most frequently identified organisms associated with outbreaks in these settings. The major route of transmission is from person to person. Risk factors include gathering of children (specifically <3 years of age), new enrollment in a center, centers that house large numbers of children, and inadequate hand hygiene facilities and practice. The single most important procedure for minimizing fecal or oral transmission of enteric pathogens is frequent hand hygiene combined with education, training, and monitoring of staff regarding infection control procedures.[66,67]

Traveler's Diarrhea

Traveler's diarrhea affects 10% to 40% of people visiting resource-limited areas during the first 2 weeks of travel.[68–70] Diverse enteric pathogens are associated with traveler's diarrhea and can be identified in 50% to 94% of persons with symptoms.[69] Bacteria (e.g., enterotoxigenic and enteroaggregative *E. coli, Campylobacter jejuni, Salmonella* spp., and *Shigella* spp.) are implicated most frequently, followed by viruses (e.g., norovirus and rotavirus)[14,69,71,72]; parasites account for a smaller percentage of infections.

Risk factors for traveler's diarrhea are young age, season of travel, eating in restaurants, and duration of stay in a resource-limited country. Children, especially those <4 years of age, are at higher risk of severe presentations of travel-related illness, including dehydration requiring hospitalization.[73–75] Travelers should use alcohol-based hand sanitizers and carefully select adequately prepared food and beverages. Children traveling to high-risk countries should be up to date on age-appropriate vaccinations including rotavirus and typhoid vaccines, if age eligible.[76] Oral, live typhoid vaccine is available for children 6 years old and older, and an inactivated, intramuscular typhoid vaccine is available for those 2 years old and older. Immunization, however, is not a substitute for careful selection of foods and beverages and adherence to hand hygiene. Destination-specific vaccine and illness prevention recommendations are available at http://wwwnc.cdc.gov/travel/destinations/list.

Travelers to resource-limited settings should be prepared to manage a potential bacterial enteric infection empirically. Azithromycin for treatment of traveler's diarrhea generally is recommended for children traveling from low-risk to such high-risk settings.[69] However, self-administered antibiotics for diarrhea have been associated with higher rates of colonization with extended-spectrum β-lactamase–producing Enterobacteriaceae, especially in travelers to South Asia and Southeast Asia.[77] Judicious use of antimicrobial agents for prevention or for treatment of mild diarrhea is recommended. Laboratory evaluation for a treatable cause should be performed on patients with the following: body temperature >101.3°F; dysentery; large-volume, watery diarrhea with any degree of dehydration; or diarrhea lasting ≥14 days.[69]

Travelers should be informed about the following: (1) the ubiquitous exposure to pathogens during travel; (2) safe foods and beverages and unsafe items, which may depend on the travel destination; (3) the need to follow appropriate rules of hygiene, including proper preparation of food, and use of hand hygiene; and (4) the importance of fluid replacement if diarrhea occurs. Travelers should also seek evaluation by a travel medicine specialist before an international trip to receive region-specific advice, vaccinations, and illness prevention recommendations (see Chapter 8).

Diagnosis

Diagnostic testing may be beneficial in guiding therapy and contributing to surveillance, but often tests are not required because most episodes of diarrhea are self-limited. The approach to a child with acute diarrhea aims to (1) assess the degree of dehydration and provide fluid and electrolyte replacement and nutrition, (2) determine whether the episode is part of an outbreak, (3) prevent spread, and (4) determine the etiologic agent, and (5) provide specific therapy if indicated. In some children, additional laboratory tests on stool specimens may be indicated.

Clinical History

A detailed clinical history is important in determining the likely cause of diarrhea, selecting appropriate testing, interpreting results, and administering anti-infective agents if necessary (Table 55.5; see Fig. 55.1).

TABLE 55.5

Clinical History Considerations When Assessing a Child With Diarrhea

Host Factors	Exposures	Characteristics of Presentation
Presence of immunodeficiency Presence of chronic disease	Childcare center attendance Travel to diarrhea-endemic area Visit to farm or petting zoo Contact with reptiles or other animals Use of antimicrobial agents Contacts with similar symptoms Food exposures: seafood, unwashed produce, unpasteurized milk or dairy products, or incompletely cooked meats	Symptom onset Duration Stool frequency and consistency Presence of mucus and blood Other associated signs and symptoms: fever, vomiting, abdominal pain, headache, and seizures

The immune status of the symptomatic child should be assessed because underlying primary or secondary immunodeficiency or chronic disease leads to consideration of special pathogens. Persistent diarrhea, defined as diarrhea lasting more than 14 days, can occur with both viral and bacterial pathogens, but infections with parasitic pathogens should also be considered. A postinfectious manifestation should be considered in children with persistent or recurrent symptoms.

Examination of Stool

Fecal leukocyte examination and stool lactoferrin detection are no longer recommended in the evaluation of infectious diarrhea. Accurate interpretation and quantification of fecal leukocytes may be difficult because of degradation during processing and uneven distribution throughout stool. Detection of fecal lactoferrin has been used in place of fecal leukocyte examination as a result of its stability during processing, but lactoferrin also is present in noninfectious inflammatory diarrhea. Furthermore, lactoferrin is present in human milk, and interpreting results of fecal lactoferrin testing can be difficult in an infant who has received human milk.

Diagnostic tests should be performed when hemolytic uremic syndrome (HUS) is suspected, when stools contain blood, during outbreaks, in children who are immunosuppressed, and for public health surveillance. When children with acute diarrhea require performance of a stool diagnostic study, the specimen should be obtained as early in the course of disease as possible.[1] All stools submitted for routine testing from patients with acute community-acquired diarrhea should be assessed for *E. coli* O157:H7 and assayed for Shiga toxin to identify non-O157 Shiga toxin–producing *E. coli* (STEC).[78] Fecal specimens that cannot be inoculated immediately can be transported to the laboratory in a non–nutrient-holding medium such as Cary-Blair transport medium to prevent drying or overgrowth of specific organisms. If a stool culture is obtained, the clinician should be aware that *Yersinia enterocolitica,* diarrhea-causing *E. coli* organisms, *Vibrio cholerae, Vibrio parahaemolyticus, Aeromonas* spp., *C. difficile,* and *Campylobacter* spp. may require special requests to ensure that the laboratory modifies its routine procedures to evaluate the sample for these organisms.

The increasing availability of nonculture diagnostic tests (e.g., enzyme immunoassay, PCR, and mass spectrometry) that are highly sensitive for bacterial, viral, and parasitic enteropathogens can dramatically decrease time to organism detection and therefore optimize management. For example, multiplex PCR testing, capable of detecting many diarrheal pathogens simultaneously, has been increasingly used in clinical laboratories.[79–81] One study showed that 3 different multiplex PCR platforms were more sensitive in detecting enteropathogens in diarrheal specimens when compared with stool culture, enzyme immunoassay, and PCR detecting a single pathogen.[80] However, multiplex PCR also increased simultaneous detection of more than one organism and organisms in nondiarrheal specimens, thus increasing the need for clinical interpretation. Disadvantages of nonculture diagnostic tests include the inability to generate susceptibility data and information needed for public health investigations including serotyping and subtyping. Studies evaluating new methods of enteropathogen detection are ongoing.

Other modalities including endoscopy, proctosigmoidoscopy, and abdominal imaging may be helpful in establishing a diagnosis in children with severe colitis, those who are immunocompromised, or those with an inflammatory enteritis syndrome of unknown origin.

Treatment

All patients with diarrhea require some level of fluid and electrolyte therapy and attention to diet. A few patients need other nonspecific support, and some may benefit from specific antimicrobial therapy.

Fluid and Electrolyte Therapy

Oral rehydration therapy (ORT) is the preferred treatment for fluid and electrolyte losses resulting from diarrhea in children with mild to moderate dehydration,[20,82] but this recommendation is not always followed when alternative forms of rehydration are available. Stool losses of water, sodium, potassium, chloride, and base must be restored in children with dehydration to ensure effective rehydration.

Since the early 1980s, studies have proven the effectiveness of glucose-electrolyte ORT solutions compared with rapidly administered intravenous therapy in children with diarrhea from causes other than cholera. Compared with children who received intravenous fluid, children who received ORT had a reduction in subsequent unscheduled follow-up visits, lower rates of complications, and comparable rates of frequency and volume of stools, duration of diarrhea, and rate of weight gain. Additional benefits of ORT include decreased cost and ease of administration in many settings, thereby reducing the need for hospitalization.[83] The WHO and the United Nations International Children's Emergency Fund (UNICEF) recommend a reduced-osmolarity formulation of ORT to avoid the risk of hypernatremia and 10 to 14 days of zinc supplementation for treatment of children with diarrhea.[84,85]

Intravenous fluid administration provides rapid resuscitation for severely dehydrated children, those who are unable to tolerate oral fluids, and those whose condition is worsening while they are receiving ORT. Isotonic solutions as maintenance fluids are preferable to hypotonic solutions. A meta-analysis of rehydration fluids used in the first 24 hours among hospitalized children showed that isotonic fluid was protective against hyponatremia in multiple settings when adjusting for age, severity of illness, and admission to a medical or surgical service.[86]

Dietary Intake

Early feeding, within 12 hours of initiating rehydration, of age-appropriate foods to children with diarrhea should be an integral component of management and is safe and effective.[87] When used with glucose-electrolyte ORT, early feeding can reduce stool output as much as cereal-based ORT. Studies of early-feeding regimens have shown that unrestricted diets do not worsen the course of symptoms of mild diarrhea and can decrease stool output compared with rehydration therapy alone. Studies of early refeeding indicate a reduction in duration of diarrhea by 0.4 days (95% confidence interval [CI], 0.1–0.7).[20] Although these beneficial effects are modest, the added benefit of improved nutrition with early feeding has major importance. During the refeeding period, certain foods, including complex carbohydrates (rice, wheat, potatoes, bread, and cereals), lean meats, yogurt, fruits, and vegetables, are better tolerated than other foods. Fatty foods and foods high in simple sugars (including juices and soft drinks) should be avoided.[20]

Antimicrobial Therapy

Antimicrobial agents are of no benefit and may have deleterious effects in children infected with enteric viruses, including rotavirus, enteric adenovirus, astrovirus, and norovirus. Children with diarrhea associated with certain bacterial and protozoal agents may benefit from therapy. Limited benefit can be achieved with therapy in people infected with *Aeromonas* species (trimethoprim-sulfamethoxazole), *Blastocystis hominis* (metronidazole or iodoquinol), *Campylobacter jejuni* (erythromycin or azithromycin, if given early in the course of therapy), *Cryptosporidium* (nitazoxanide), or intestinal microsporidia (albendazole).[21] Antimicrobial therapy of immunocompetent children with intestinal salmonellosis or *Y. enterocolitica* infection is of no known benefit, except possibly for infants <3 months of age. A matched case-control study of patients <20 years of age in Minnesota with *E. coli* O157:H7 gastroenteritis showed that those who developed HUS were more likely to have received a β-lactam antibiotic (penicillin or cephalosporin) compared with those who received other classes of antibiotics or no antibiotics (odds ratio = 17.1; 95% CI, 2.2–135.0).[88] A larger prospective cohort study of 259 children with *E. coli* O157:H7 infection showed that exposure to any antibiotic was associated with greater HUS rates (36% vs. 12%; P = 0.001) and greater oligoanuric HUS rates (12% vs. 3%; P = 0.005).[89] The evidence accumulated to date suggests that certain classes of antibiotics in children with *E. coli* O157:H7 infection should be avoided.

Adjunctive Therapy

Various pharmacologic agents have been used as nonspecific therapy for people with acute infectious diarrhea (Table 55.6). These compounds can be classified according to the following mechanisms of action: (1) alteration of intestinal motility, (2) alteration of secretion, (3) adsorption of toxins or fluid, and (4) alteration of intestinal microflora. Many of these compounds, especially agents that alter motility, have systemic toxic effects that are augmented in infants and children. Most of these agents are not approved for children <3 years of age. Few published data are available to support use of most antidiarrheal agents to treat acute diarrhea, especially in children.[20,90,91]

TABLE 55.6

Adjunctive Therapies for Reduction of Diarrheal Symptoms in Children

Mechanism	Example	Recommended Age
Alteration of intestinal motility	Loperamide	≥6 yr
	Difenoxin and atropine	≥2 yr; requires prescription
	Diphenoxylate and atropine	≥2 yr; requires prescription
	Ondansetron (for nausea and vomiting)	≥4 yr
Alteration of secretion	Bismuth subsalicylate	≥12 yr
Alteration of intestinal microflora	Probiotics (e.g., *Lactobacillus, Saccharomyces, Bifidobacterium*), fecal biotherapy or transplant	Any age
Bowel nutritional support	Zinc	Any age

Zinc has been shown to decrease the duration of acute diarrhea by 20%,[92] improve intestinal permeability, and improve short-term recovery from intestinal injury[93] when consumed by children residing in low-resource countries.

Use of probiotics has been shown to be effective in randomized clinical trials for treating acute viral gastroenteritis in previously healthy children and modestly effective in preventing antibiotic-associated diarrhea in healthy children. Despite heterogeneity among studies, children receiving *Lactobacillus* GG in an emergency department had a median duration of diarrhea of 51 hours (interquartile range, 45–120 hours) versus 74 hours (interquartile range, 32–78 hours) compared with children who received placebo (P = 0.02).[94] Length of hospitalization was decreased by 1.1 days (95% CI, 0.4–1.2) among children who consumed a probiotic in 10 studies comprising a systematic review involving 1932 children.[95] The consumption of human milk by infants during episodes of diarrhea is recommended for its complete nutritional source, for delivery of prebiotics and probiotics, and for optimizing anti-inflammatory effects on intestinal epithelia. Continued evaluation of specific probiotic products, in well-designed clinical trials involving infants and children, will be needed to develop definitive recommendations for the use of prebiotics and probiotics.[96,97]

Fecal biotherapy, or stool transplantation, has been used in patients with refractory or relapsing *C. difficile* infections. Various delivery methods, including duodenal or colonic instillation, nasogastric tube, and capsules containing fecal flora, have been used. Donors are screened before stool donation and have included healthy volunteers, intimate partners, household members, and relatives. Adverse events are uncommonly reported and are mild. Studies have shown that fecal biotherapy was curative for 90% of adults and for 70% to 90% of children with refractory or recurrent *C. difficile* infection.[98–100] Optimal dosing, donor selection, and method of delivery are areas of active investigation.

Prevention

The most important aspect in the prevention and control of diarrheal disease is hygiene, both public and personal. These measures include meticulous hygiene, food preparation techniques,[66] and limited use of antacids, antimotility drugs, and antimicrobial agents. Ergonomically conducive diaper-changing facilities and reinforcement of hygienic diaper-changing techniques should be available and implemented in childcare centers. Written infection control policies must be in place and adhered to in all healthcare and childcare facilities. Guidelines for preventing opportunistic gastrointestinal infections in children with HIV infection and recipients of hematopoietic stem cell and organ transplants are published,[61,62] as are guidelines to prevent disease associated with pets in the home and exposure to animals in public settings.[101]

Human milk consumption provides young infants with significant protection against morbidity and death from diarrheal disease.[102] Immunologic components such as secretory IgA, oligosaccharides, glycoconjugates, and lactoferrin in human milk protect infants against disease after exposure to an infectious agent.[103]

Currently, vaccines to prevent typhoid, rotavirus infection, and hepatitis A are recommended for administration to children and adults meeting certain age and exposure parameters in the US that can be found at http://www.cdc.gov/vaccines/hcp/acip-recs/index.html. Candidate vaccines against enteric pathogens, agents that may interfere with microbial adherence or virulence mechanisms, and compounds that serve as competitors for binding of organisms or toxins to intestinal receptors are being studied.[104–106] Applications of glycoconjugates, probiotics, and fecal biotherapy in diarrheal disease prevention are active areas of investigation.[107,108]

Key Points

Gastrointestinal Tract Infections

Epidemiology

- Diarrhea is an important cause of childhood morbidity and mortality.

- Children are at risk of morbidity and death as a consequence of infectious diarrhea.

- Premature infants, infants living in crowded settings, and children with underlying immune deficiencies are at greater risk of disease.

Diagnosis

- Obtaining a thorough history is important in determining the cause, appropriate diagnostic testing, and treatment.

- Diagnostic testing should be considered if stools contain blood, during outbreaks, in people who are immunosuppressed, when hemolytic uremic syndrome is suspected, and for public health surveillance.

Treatment

- Low-osmolarity oral rehydration therapy is recommended for management of children with mild to moderate dehydration associated with diarrhea.

- Early refeeding of age-appropriate foods is recommended.

- Antibiotics are unlikely to be effective in the management of the most common causes of viral and bacterial diarrhea and may contribute to antibiotic-associated diarrhea.

Prevention

- Hygiene, both public and personal, is the most important aspect in the prevention and control of diarrheal disease.
- Vaccines to prevent rotavirus and hepatitis A infections are recommended for age-eligible children.
- Vaccine to prevent typhoid is recommended for age-eligible children who travel to a typhoid-endemic area.

Viral Gastroenteritis

Eyal Leshem, Ben A. Lopman

Viral agents are the most common causes of acute gastroenteritis, a syndrome of acute vomiting and diarrhea associated with inflammation of the stomach, small intestines, or large intestines. Among children, viral gastroenteritis remains a leading cause of pediatric morbidity and mortality worldwide.[1,2] With the discovery of norovirus[3] and rotavirus[4] in the early 1970s, and subsequent development of improved diagnostic strategies for these and other enteric viruses,[5,6] the importance of viral agents as causes of diarrheal disease has been increasingly appreciated. The global introduction of highly effective rotavirus vaccines has resulted in substantial reductions in the burden of rotavirus gastroenteritis and recognition of norovirus as a major cause of acute gastroenteritis.[7–12]

Etiologic Agents

A small group of viruses accounts for most cases of acute gastroenteritis among children. These include group A rotaviruses, human caliciviruses (including noroviruses and sapoviruses), enteric adenoviruses (types 40 and 41), and human astroviruses.[7] Other viruses frequently are detected in children suffering from diarrheal illnesses; however, the prevalence of many of these other viruses in healthy children has not been determined, and therefore a causal association with diarrhea has not been established.

Rotaviruses (family Reoviridae) are 100-nm particles consisting of an outer capsid, an inner capsid, and a core.[13] The double-stranded

RNA genome is composed of 11 segments that code for 6 structural proteins and 6 nonstructural proteins. The outer capsid is composed of 2 proteins: VP7 (G protein, for glycoprotein) and VP4 (P protein, for protease-cleaved protein). These proteins are the principal antigens to which neutralizing antibodies are directed and account for the classification scheme for rotavirus strains.[14]

Caliciviruses are nonenveloped, 27- to 40-nm, single-stranded RNA viruses in the family Caliciviridae.[15] Human caliciviruses are divided into 2 genera: norovirus and sapovirus. Noroviruses include numerous genetically related viruses, further divided into 6 genogroups (I–VI), 3 of which (I, II, and, rarely, IV) are associated with human disease. At least 9 and 22 genotypes, respectively, have been identified for genogroups I and II.[16] Despite this extensive genetic diversity among noroviruses, genogroup II genotype 4 (GII.4) viruses are the most common causes of norovirus outbreaks worldwide[17]; the emergence of new GII.4 strains occurs every 2 to 4 years and can be associated with a global increase in gastroenteritis outbreaks.[18–20] Efforts to cultivate noroviruses in available cell culture systems or to develop an animal model have been unsuccessful, and this failure has hampered the development of simple diagnostic tests and the evaluation of disinfectants.[21] Important progress has been made by using B cells, but this system is not widely available.[22]

Astroviruses are nonenveloped, 28-nm, single-stranded RNA viruses in the family Astroviridae. Until 2008, human astroviruses were thought to be limited to 8 closely related genotypes (serotypes), now referred to as the “classic” human astroviruses (HAstV 1–8). HAstV genotype 1 is most commonly detected, followed by types 2 to 5; however, more than a single serotype usually circulates in communities during each season.[23] Non–type 1 viruses can predominate in a season, and greater serotype diversity can be found in developing countries.[23–25]

Adenoviruses are 70- to 100-nm, nonenveloped, double-stranded DNA viruses in the family Adenoviridae.[26] Although 7 species of adenoviruses (classified as HAdV A–G) containing at least 51 different genotypes can cause human infection, species F (genotypes 40 and 41) adenoviruses typically cause gastroenteritis.[27]

Many studies report the detection of viruses in stool samples from children with diarrheal illness. A key method to establish a causal association between a virus and a disease is to observe a higher prevalence among children with gastroenteritis compared with asymptomatic children (Table 56.1).

TABLE 56.1

Positivity Rates of Viral Pathogens Among Children <5 Years of Age With Acute Gastroenteritis and Healthy Controls: United States, 2008 to 2009[7]

Agent	Acute Gastroenteritis (N = 1564) No. (%)	Healthy Controls (N = 1000) No. (%)
Group A rotaviruses	282 (18)	2 (<1)
Noroviruses	334 (21)	40 (4)
Adenoviruses 40/41	186 (12)	18 (2)
Sapoviruses	80 (5)	42 (4)
Parechoviruses	76 (5)	44 (4)
Astroviruses	75 (5)	30 (3)
Bocaviruses	22 (1)	24 (2)
Aichiviruses	4 (<1)	0 (0)

Many other viruses have been found in fecal specimens, but the data are inconclusive regarding the pathogenicity for many of these viruses. Reports of the clinical characteristics of patients infected with the severe acute respiratory syndrome (SARS) coronavirus and with the more recently described Middle East respiratory syndrome (MERS) coronavirus have noted diarrhea in approximately one fourth of cases.[28,29]

Epidemiology

All the major enteric viruses are transmitted primarily through close person-to-person contact by the fecal-oral route.[30] Noroviruses, in addition, are easily spread through contaminated food and water and therefore are major causes of foodborne disease.[31–33] Noroviruses are present in the vomitus of ill people, and droplet spread through exposure to vomitus has been demonstrated to be a mechanism of spread in both healthcare and public settings.[34–36] Contact with a symptomatic child is a major determinant of norovirus infection. Children <5 years of age seem to be more contagious than older children and adults and therefore play key roles in norovirus transmission to all age groups.[37] The modes of transmission of adenoviruses are less well understood, but transmission is presumed to occur primarily through close contact by fecal-oral spread. Spread through fomites is possible for each of the agents, and it can play an important role in disease acquired in institutional and group childcare settings.[38]

Common viral gastroenteritis viruses are globally distributed. Although traditionally temperate climates are associated with a strong winter peak of rotavirus, a meta-analysis showed that the level of country development was a stronger predictor of seasonality than was geographic location or climate.[39] Since the introduction of routine vaccination in the United States, the rotavirus season has diminished substantially in magnitude, and it has also been delayed in some years.[12,40] A biennial pattern of lower, delayed rotavirus seasons followed by slightly higher peaks has emerged in the US. (Fig. 56.1).[12,40,41] In low-income and tropical settings, rotaviruses typically circulate year-round.[39,42,43] Noroviruses circulate year-round in most areas, but a clear wintertime seasonality to outbreaks is present, particularly in healthcare settings.[31,44,45] Astroviruses typically peak during winter and sapoviruses peak during early spring months in temperate countries.[7,46] The seasonality of adenoviruses is less distinct, and transmission has been described year-round, with summertime epidemics.[7,47]

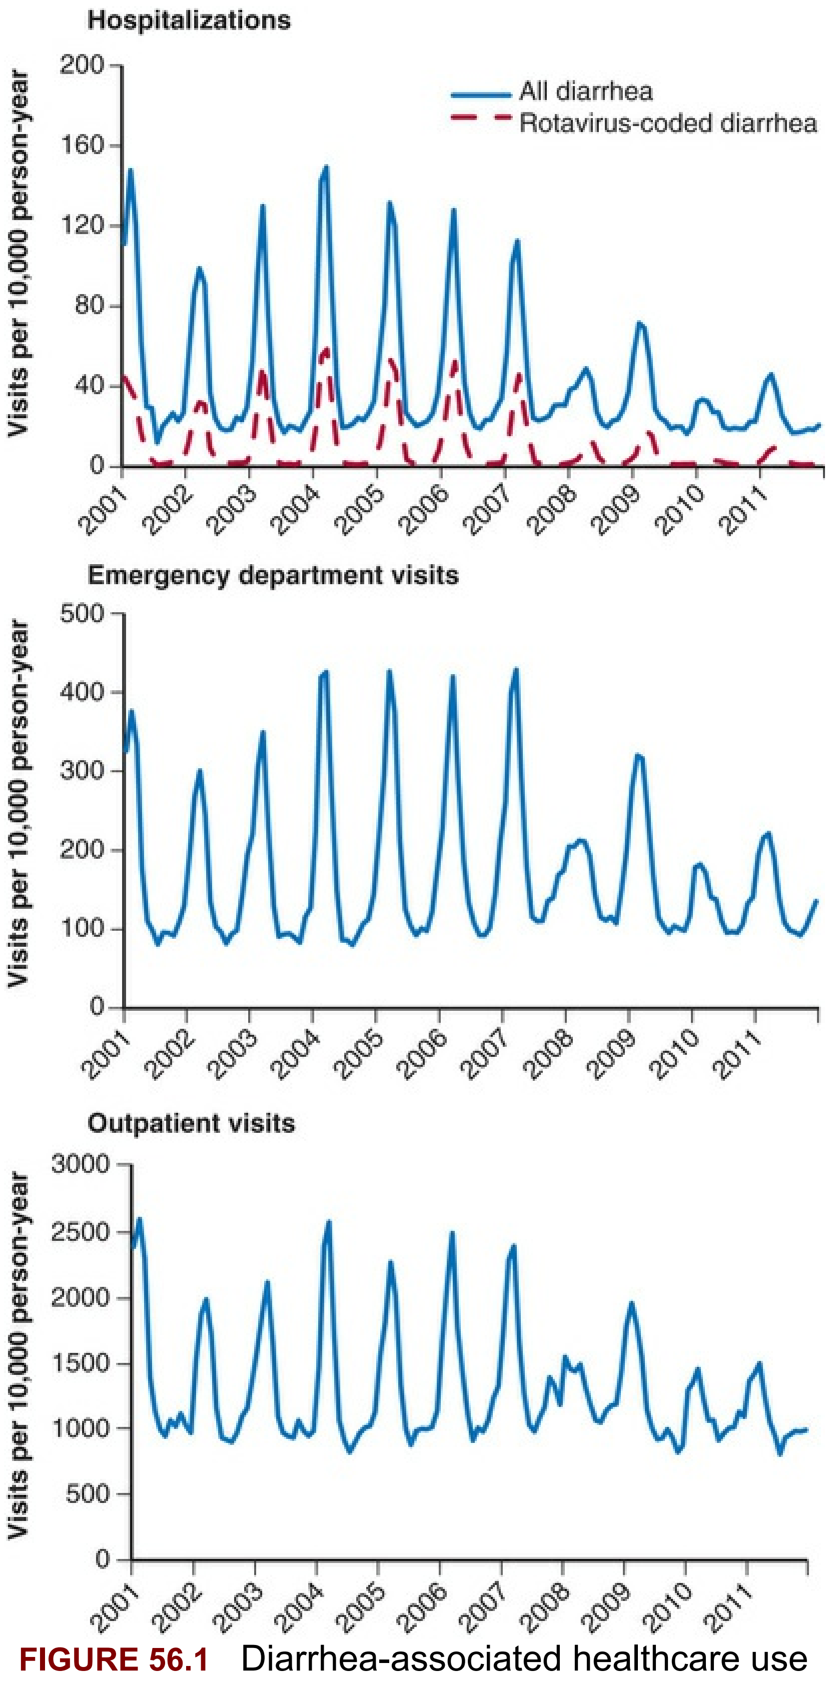

FIGURE 56.1 Diarrhea-associated healthcare use rates among United States children <5 years of age, 2001 to 2011. (From Leshem E, Moritz RE, Curns AT, et al. Rotavirus vaccines and health care utilization for diarrhea in the United States (2007–2011). Pediatrics 2014;134(1):15–23.)

The highest rates of severe rotavirus infections occur in the first 2 years of life; most hospitalizations and severe dehydrating disease occur between 4 and 23 months of age.[48–50] Infections in the first 3 months are less common and are often asymptomatic, probably because of protection from maternally acquired antibodies.[48,51] Rotaviruses can infect children more than once, with each subsequent infection less severe as a result of immunity that develops following infection.[48] Severe rotavirus disease among older children and adults is less common, but infection can occur in people exposed to younger children in childcare settings and schools. Outbreaks also occur in long-term care facilities.[52]

Before the introduction of rotavirus vaccines, rotaviruses accounted for 25% to 50% of hospitalizations for gastroenteritis among children <5 years of age and for 5% to 20% of milder cases in people who sought care in clinics.[49,53] Following vaccine introduction, the rates of rotavirus-associated healthcare use substantially decreased (see Fig. 56.1).[11,12] Population-based surveillance in the US detected rotavirus in 13% of children hospitalized for gastroenteritis and in 6% of pediatric outpatient visits for gastroenteritis.[11] Globally, rotavirus causes approximately 500,000 deaths/year in children less than 5 years of age, and deaths among children in the poorest countries account for more than 85% of the total.[1,54] In middle-income countries (Mexico and Brazil) where rotavirus vaccines were introduced in 2006, sustained reductions were documented in diarrhea-associated pediatric mortality rates (Fig. 56.2).[9,10] Rotavirus-associated death is rare in developed countries.[55,56]

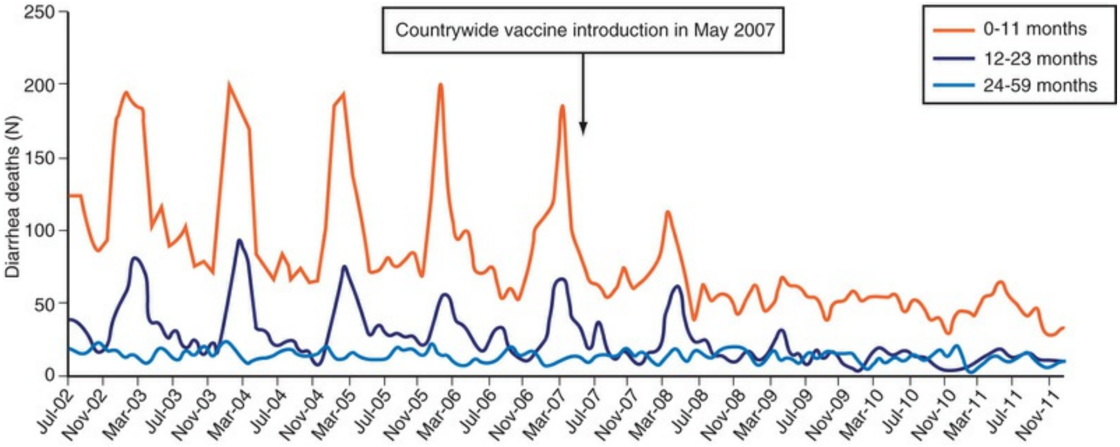

FIGURE 56.2 **Number of diarrhea-related deaths among children aged**

<5 years from July 2002 through December 2011 in Mexico according to age group. (From Gastanaduy PA, Sanchez-Uribe E, Esparza-Aguilar M, et al. Effect of rotavirus vaccine on diarrhea mortality in different socioeconomic regions of Mexico. Pediatrics 2013;131(4): e1115–1120.)

Noroviruses now are recognized as the most common causes of both endemic disease and outbreaks of gastroenteritis.[11,32,57] Noroviruses are estimated to cause 19 to 21 million illnesses a year in the US that result in 1.7 to 1.9 million outpatient visits, 400,000 emergency department visits, 56,000 to 71,000 hospitalizations, and 570 to 800 deaths.[32] Globally, norovirus is estimated to cause 18% of the cases of severe diarrheal disease in children <5 years old (17% of inpatient cases and 24% of community episodes).[58] Following the introduction of rotavirus vaccines and the subsequent decline in rotavirus disease burden, noroviruses have overtaken rotavirus to become the predominant causes of severe gastroenteritis in the pediatric population.[11,59,60] Among children <5 years old who were studied in an active surveillance network in the US, norovirus accounted for 21% of gastroenteritis cases requiring medical attention, including 17% of children admitted to the hospital and 28% of outpatients (see Table 56.1).[11]

All age groups are affected by noroviruses, but the disease incidence is highest in children <5 years of age.[61] Noroviruses are the most commonly reported causes of foodborne disease in the US, whereas internationally, estimates vary widely.[32,62] Common foods associated with outbreaks include those that are uncooked or handled after cooking (which can be contaminated by ill food handlers), as well as shellfish harvested from contaminated water. Healthcare facilities, including nursing homes and hospitals, are the most common settings of norovirus outbreaks; other environments such as childcare facilities and cruise ships are frequently affected.

Sapoviruses are most commonly associated with sporadic gastroenteritis, usually among young children.[63,64] Outbreaks caused by sapoviruses are less common and tend to occur in older adults.[65] Sapoviruses were detected in approximately 10% of all gastroenteritis episodes in England and Finland and in 4% of hospitalized cases in Finland among children <2 years of age.[66,67] In the US, sapoviruses were detected in 5% of pediatric diarrhea cases compared with 4% among healthy controls ($P < 0.01$) (see Table 56.1).[7] Sapovirus infections tend to be less severe than norovirus infections; vomiting is common, and diarrhea may not be present.[7,67]

Although astroviruses have been detected in all age groups, most infections are in children <2 years of age and tend to be less severe than rotavirus infections.[68] Serosurveys in the US have shown that >90% of children have antibodies to human astroviruses by 6 to 9 years of age.[69] Disease in adults is uncommon, but it can occur in outbreak settings.[70] Astroviruses are usually detected in <10% of young children treated for gastroenteritis in outpatient clinics or in hospitals, but these viruses are occasionally found at higher frequencies.[7,47,71] Although astroviruses primarily cause sporadic disease, outbreaks have been reported in a range of settings, and astroviruses can be common causes of nosocomial gastroenteritis in children's hospitals.[72]

Most enteric adenovirus infections occur in children <2 years of age, and these viruses appear to be less important causes of gastroenteritis among adults.[7,73,74] Enteric adenoviruses were shown to account for 5% to 12% of hospitalizations for acute gastroenteritis in children and can be common causes of healthcare-associated diarrhea.[7,75] Enteric adenoviruses are detected in 1% to 12% of children with community-associated diarrhea.[7,76,77]

Pathogenesis

After oral inoculation, viruses infect cells of the small intestinal villi.[78] Infection of the mature villous enterocytes, which have both digestive and absorptive functions, leads to cell death and sloughing of the villus cells. In a normal host, infection resolves as the number of susceptible mature enterocytes decreases secondary to cell death and as the host generates an immune response. Viruses are shed in the stool during the acute illness in large quantities. Rotaviruses, noroviruses, and astroviruses can also be shed for 1 to 2 days before illness and for several days following resolution of symptoms.[30,38] Although viral gastrointestinal infections are generally confined to the intestine, rotavirus and norovirus infections can result in antigenemia and the presence of nucleic acid in blood of ill patients, but extraintestinal disease is rare.[79,80] Asymptomatic infection is common, especially for norovirus,[66] and is thought to play a role in disease transmission.[81]

Immunity to rotavirus is acquired, and multiple infections typically are required until the child is fully protected against disease.[48,82,83] After a primary infection, homotypic immunity is stronger, but immunity seems to broaden to other serotypes with subsequent infections.[48] Wide estimates of the duration of immunity to norovirus range from 6 months to 4 to 9 years after natural infection occurs; however, heterotypic immunity may be limited.[37,84] Because diarrheal disease caused by astrovirus, adenovirus, and sapovirus is largely restricted to children, immunity is believed to be long-lasting.

A correlation exists between the expression of histo–blood group antigens (HBGAs) and susceptibility to norovirus and possibly rotavirus infections.[85–92] HBGAs comprise a diverse family of carbohydrates expressed on the mucosal epithelia of the respiratory, genitourinary, and digestive tracts; HBGAs are recognized as receptors allowing norovirus attachment and cellular entry. The expression of HBGAs is determined by 3 gene families expressing the *ABO* (A/B enzymes), secretor *(FUT2)* gene, and Lewis-type *(FUT3)* gene. Single nucleotide gene polymorphisms can inactivate the expression of these gene products, thereby breaking a link in the norovirus binding and infection process. Mutations in the *FUT2* gene leading to the absence of HBGA expression (nonsecretor phenotype) have been associated with resistance to infection, in particular to GII.4 noroviruses, which are the predominant global genotype.[85,86,88,89,93–96] HGBA expression appears to vary by ethnicity; 20% to 25% of the US. white population consists of nonsecretors compared with 2% of persons of Meso-American or Hispanic ancestry. In East Asia, different secretor mutations (*A385T* and *FUT3*) observed in Chinese and Vietnamese children confer lower risk of norovirus infections.[91,97] Evidence points to lower susceptibility of nonsecretors to rotavirus infections in various populations.[90–92]

Clinical Manifestations

Although these viruses differ genetically and structurally, the clinical presentations of acute gastroenteritis caused by these agents are indistinguishable. After a short incubation period, infections with any of the viruses lead to an acute onset of gastroenteritis

(Table 56.2). Vomiting is often an early sign, common in rotavirus infection, and particularly pronounced in norovirus and sapovirus infections.[7,98] Typically diarrhea is watery, and without blood, mucus, or fecal leukocytes. Fever occurs in approximately half of children with rotavirus infection and in approximately one fourth of children with nonrotavirus viral gastroenteritis, and it is often an early sign. Vomiting and fever frequently cease within 1 to 3 days, whereas diarrhea can persist longer, especially in rotavirus infections. Other symptoms include abdominal cramps, malaise, and seizures.[7,99]

TABLE 56.2

Epidemiologic Features of Viral Causes of Gastroenteritis

Feature	Rotavirus	Noroviruses	Sapoviruses	Astroviruses	Adenoviruses
Predominant age of illness	<5 yr	All ages	<5 yr	<2 yr	<2 yr
Mode of transmission	Person-to-person through fecal-oral route, fomites	Person-to- person through fecal-oral and vomitus-oral, fomites, food or water	Person-to-person through fecal-oral route	Person-to-person through fecal-oral route	Person-to-person through fecal-oral route
Incubation period	1–3 days	12–48 hr	12–48 hr	1–4 days	3–10 days
Symptoms					
Diarrhea	Explosive, watery	Watery with acute onset	Watery; milder than rotavirus	Watery; milder than rotavirus	Watery; milder than rotavirus; can be prolonged
Vomiting	80%–90%	>50%; often dominant symptom	Less common than rotavirus	Less common than rotavirus	Less common than rotavirus
Fever	Frequent	Less common, usually mild	Less common, usually mild	Less common, usually mild	Less common, usually mild
Illness duration	2–8 days	1–5 days	1–4 days	1–5 days	3–10 days
Clinical diagnosis	Stool EIA or LPA	RT-PCR	RT-PCR	Stool EIA (not available in United States)	Stool EIA

EIA, enzyme immunoassay; LPA, latex particle agglutination; RT-PCR, reverse transcriptase–polymerase chain reaction.

Modified from Peck AJ, Bresee JS. Viral gastroenteritis. In: McMillan JA, Feigin RD, De Angelis CD, Jones MD Jr (eds). Oski's Pediatrics, 4th ed. Philadelphia, Lippincott Williams & Wilkins, 2006, pp. 1288–1294.

The most important and common complication of viral gastroenteritis is dehydration, often associated with electrolyte abnormalities. Malabsorption can occur during the illness and persist for weeks following infection. Extraintestinal complications are rare, but encephalitis, seizures, acute myositis, hemophagocytic lymphohistiocytosis, acute flaccid paralysis, and sudden infant death syndrome have been described in children with rotavirus infections.[13,99,100] The association of these complications with rotavirus infection remains unclear. Severe and prolonged diarrhea associated with each agent has been reported among children with malnutrition and among children with congenital or acquired immunodeficiencies.[101–105]

Although viral causes of gastroenteritis are not distinguishable by clinical signs and symptoms, clinical characteristics of cases in outbreak settings have been helpful in predicting the presence of noroviruses. Kaplan and colleagues[98] found that outbreaks that met simple epidemiologic and clinical criteria were likely to have been caused by noroviruses. These criteria included (1) failure to detect a bacterial or parasitic pathogen in stool specimens, (2) the occurrence of vomiting in >50% of patients, (3) mean duration of illness of 12 to 60 hours, and (4) mean incubation period of 24 to 48 hours. The "Kaplan criteria" have been validated and are used by local health departments for the diagnosis of outbreaks in the absence of laboratory testing for norovirus.[106]

Diagnosis

Laboratory diagnosis of viral gastroenteritis is made by detection of viral antigen or nucleic acid in fresh, whole stool samples obtained during the acute illness. Commercially available assays to detect rotavirus antigen in stools offer easy and inexpensive methods to diagnose infection in children. These tests are available as either enzyme immunoassay (EIA) or a latex particle agglutination test for group A rotaviruses, designed to detect the VP6 protein.[13] Antigen detection tests generally have high (90% to 95%) sensitivity and specificity.[93] Other methods of rotavirus detection include electron microscopy, viral isolation, and RNA polyacrylamide gel electrophoresis. Reverse transcription–polymerase chain reaction (RT-PCR) is rarely used in clinical practice because of the test's high sensitivity; it may detect virus when that virus is not causing disease.[107] Serologic testing for rotavirus infection is possible but impractical and thus is not widely available in clinical care settings.

Real-time RT-PCR is the preferred laboratory method for detecting noroviruses. This assay is highly sensitive and can detect as few as 10 norovirus copies per reaction and provide a semiquantitative estimate of viral load. The assay is generally used to detect norovirus in stool, but it can also be used for vomitus, foods, water, and environmental specimens for outbreak investigations, although with reduced sensitivity. Conventional PCR followed by sequence analysis of the PCR products is used for norovirus genotyping.[108] Given the exquisite sensitivity of RT-PCR for norovirus and the high frequency that the virus can be found in healthy persons,[11,66,109] diagnostic results should be interpreted in light of clinical characteristics and, if available, the background level of detection in a control population. A commercial EIA for norovirus was approved in the US in 2011; however, this assay has low sensitivity and is not recommended for diagnosing norovirus infection in sporadic cases. Norovirus EIA can be useful in outbreak investigations.[110–112]

Commercial EIAs for detection of astrovirus viral antigen in stool are available in Europe, but not in the US. RT-PCR is a sensitive and specific method for detection of astroviruses.[113] RT-PCR, serologic assays, and electron microscopy are used primarily in research settings. Similarly, RT-PCR, EIA, and latex particle agglutination kits are available commercially and provide highly sensitive and specific antigen detection of enteric adenoviruses.[26] All viral agents of gastroenteritis are detectable by electron microscopy and immune electron microscopy, but these tests are seldom used because of their relatively low sensitivity and specificity, expense, and required expertise.

Treatment

No specific therapies are available for viral gastroenteritis. Case management depends on accurate and rapid assessment of the severity of dehydration, correction of fluid loss and electrolyte disturbances, and maintenance of adequate hydration and nutrition.[113] Treatment with oral rehydration solution (ORS) containing appropriate glucose-electrolyte solutions is sufficient for most patients. ORS use a protein sodium-glucose cotransporter 1 (SGALT1) that facilitates solute absorption across the luminal membrane. Water passively follows the osmotic gradient generated by transcellular transport of electrolytes and nutrients. In 2004, the World Health Organization recommended use of low-osmolarity ORS (245 mOsm/L), which has been shown to decrease stool output and vomiting in comparison with children treated with traditional ORS (311 mOsm/L). Intravenous rehydration can be required for children with severe dehydration (≥10% fluid deficit, shock, or near shock), intractable vomiting, or ORS treatment failure. Factors such as young age, unusual irritability or drowsiness, progressive course of symptoms, or uncertainty of diagnosis can indicate a need for close observation.

Breastfed infants should continue to nurse on demand. In children who are not breastfed, change to a lactose-free diet may result in earlier resolution of acute diarrhea and reduce treatment failure.[114] Children taking solid foods should continue to receive their usual diet during episodes of diarrhea, although substantial amounts of foods high in simple sugars should be avoided because the osmotic content may worsen diarrhea. Evidence on the use of oral probiotics (e.g., *Lactobacillus* spp.) to reduce the duration of diarrhea caused by rotavirus is conflicting.[115–117] Zinc, used both as supplement and treatment, reduces the severity, duration, and incidence of diarrhea in low- to middle-income settings and is considered one of the mainstays of treatment in developing countries[118,119]; however, the role of zinc supplementation in high-income settings has not been extensively studied. Because viral agents account for most cases of infectious gastroenteritis in children, antimicrobial therapy is not usually indicated for children (see Chapter 55).[120]

Prevention

The best public health intervention to reduce the incidence of severe viral gastroenteritis is the implementation of live, oral rotavirus vaccines in routine immunization programs. Rotavirus vaccines are attenuated strains given in multiple doses designed to replace a child's first exposure to wild-type rotavirus with strains that will not cause disease but will generate an adequate immune response to confer protection. Currently, 2 rotavirus vaccines are licensed in the US.[121] A third vaccine has been evaluated in India.[122] Additional vaccines are in development and may be available within several years.

As of 2015, rotavirus vaccines have been added to routine immunization programs in more than 75 countries, and these vaccines exert a dramatic impact with rapid and sustainable reductions in diarrhea-associated healthcare use and acute gastroenteritis–associated mortality rates.[9,10,12,40,123] Vaccine efficacy was shown to be very high in high- and middle-income settings and moderate in low-income populations[124–128]; however, vaccines may have their greatest impact in these low-income settings because of the higher burden of disease. The World Health Organization issued a global recommendation for the use of rotavirus vaccines.[129] Vaccine effectiveness in real-life routine use across various demographic and geographic settings has been good.[130,131]

Except for rotavirus, prevention of viral gastroenteritis is limited to nonspecific strategies. Breastfeeding confers some protection against rotavirus infection, and probably other viral infections, in young infants. Good hygiene, including meticulous handwashing practices, is an effective prevention strategy and should be encouraged, particularly in institutional settings, such as childcare centers and hospitals.[132] Significantly reducing transmission of viral agents of gastroenteritis requires strict adherence to recommendations because of the low infectious dose and the high quantity of viruses excreted in stool (and often vomitus) from infected persons and because these viral agents are quite stable in the environment. Noroviruses are relatively resistant to environmental disinfection; cleaning contaminated surfaces and food preparation areas with Environmental Protection Agency–approved cleaners is effective in settings where viral gastroenteritis outbreaks occur.[132,133]

Although experimental vaccines against noroviruses are in development, proof that these vaccines could protect against natural infection remains to be established.[134,135] These vaccines are based on virus-like particles and showed promise in volunteer challenge studies when they were administered both intranasally and intramuscularly. No vaccines against other viral gastroenteritis agents are yet in human trials.

Key Points

Epidemiology, Clinical Features, Diagnosis, Treatment, and Prevention of Viral Gastroenteritis

Epidemiology

- Viruses account for most cases of acute gastroenteritis among children. These include rotaviruses, noroviruses, enteric adenoviruses (types 40 and 41), astroviruses, and sapoviruses.

- Viral gastroenteritis occurs in endemic and epidemic forms. Rotaviruses and noroviruses are the major causes of endemic disease, with seasonal peaks during the winter months in temperate climates. Noroviruses are the main causes of epidemic disease.

- Following introduction of rotavirus vaccine, rates of rotavirus gastroenteritis have decreased substantially, and currently noroviruses are the major causes of acute gastroenteritis in the United States.

Clinical Features

- The clinical characteristics of illnesses caused by different viruses generally are indistinguishable. These include watery diarrhea and, in some cases, vomiting and fever.

- The most common severe complication of viral gastroenteritis is dehydration, often with electrolyte abnormalities.

- Prolonged diarrhea has been reported among children with malnutrition and among immunocompromised patients.

Diagnosis

- Laboratory diagnosis of viral gastroenteritis is best made by detection of viral antigen or nucleic acid in fresh, whole stool samples obtained during the acute illness.

- Commercially available assays to detect rotavirus antigen in stools offer an easy and inexpensive method to diagnose infection in children.

Treatment

- No specific therapies are available for viral gastroenteritis.
- The mainstays of therapy include assessment of dehydration severity, correction of fluid loss and electrolyte disturbances, and maintenance of adequate nutrition.
- Oral rehydration using oral rehydration solution with appropriate glucose-electrolyte solutions is sufficient for most patients.
- Zinc is used for treatment in low-income countries.

Prevention

- Rotavirus vaccines have been added to routine immunization programs in more than 75 countries and have substantially reduced diarrhea-associated healthcare use and acute gastroenteritis-associated mortality rates.
- Except for rotavirus, prevention of viral gastroenteritis is limited to nonspecific strategies including breastfeeding, hand hygiene, and strict adherence to hygiene guidelines including use of Environmental Protection Agency–approved cleaners for food preparation areas and contaminated surfaces.

Inflammatory Enteritis

David A. Blanco, Harpreet Pall

Inflammatory enteritis is a pathologic diagnosis characterized by ileal or colonic inflammation, or both, which can range from small, superficial patches of leukocyte infiltration amid relatively normal mucosa to deep, exudative ulcerations with involvement of the entire intestinal wall.[1] The large number of infectious and noninfectious causes of inflammation results in a wide range of manifestations. Inflammatory enteritis should be considered in the differential diagnosis of patients with abdominal pain, dysentery, or watery diarrhea, particularly when patients come to attention with fever and blood or mucus in stool.

Classification

Inflammatory enteritides can be classified into several distinct clinical entities. Recognition of these entities facilitates suspicion of etiologic agents (Table 57.1), as well as diagnosis and management. However, many patients with inflammatory enteritis do not fit easily into any of these categories, thereby broadening the differential diagnosis.

TABLE 57.1

Differential Diagnoses of Inflammatory Enteritis

Acute Inflammatory Enteritis	Chronic Inflammatory Enteritis (≥2 Wk)	Proctitis
BACTERIAL	**BACTERIAL**	**MULTIPLE CLASSES**
Aeromonas hydrophila *Campylobacter jejuni or coli* Enteroaggregative *Escherichia coli* Enterohemorrhagic *E. coli* Enteroinvasive *E. coli* *Plesiomonas shigelloides* *Salmonella* spp. *Shigella* spp. *Vibrio parahaemolyticus* *Yersinia enterocolitica*	*Campylobacter jejuni or coli* Enteroaggregative *Escherichia coli* *Mycobacterium tuberculosis* *Salmonella* spp. *Shigella* spp. **FUNGAL** *Candida* spp. *Histoplasma capsulatum* *Paracoccidioides brasiliensis* Phycomycosis agents[a]	*Chlamydia trachomatis* *Entamoeba histolytica* Herpes simplex virus *Neisseria gonorrhoeae* *Shigella* spp. *Treponema pallidum* Other enteric pathogens[a]
PARASITIC		
Balantidium coli		
Cryptosporidium parvum[a]		
Entamoeba histolytica		
Schistosoma species		
Strongyloides stercoralis		
Trichinella spiralis		
VIRAL		
Cytomegalovirus[a]		
Enteroviruses[a]		

[a] Primarily in immunocompromised patients.

Acute dysentery is defined by the presence of fecal blood and mucus associated with frequent, small loose bowel movements. Fever often is present. Dysentery is the result of microbial invasion of the colonic mucosa, with mucosal and submucosal inflammation and destruction. Shigellosis is a prototype of acute dysentery.

Chronic inflammatory enteritis typically is an indolent and slowly progressive illness. The patient can have fever, abdominal pain, and weight loss over several weeks. Recurring, relapsing symptoms commonly occur. *Mycobacterium tuberculosis* is a classic cause of chronic inflammatory enteritis; children in the United States with chronic inflammatory enteritis are more likely to have inflammatory bowel disease.

Ulcerative proctitis is characterized by severe anorectal pain, purulent discharge, tenesmus, hematochezia, constipation, and fever. Erythematous, friable mucosa is visualized in the rectal vault.[2–4] Severe disease can lead to rectal abscesses or fistulas. This condition, which occurs primarily in men who have sex with men and in immunocompromised patients, can be caused by a variety of sexually transmitted and other infectious agents[4] (see Table 57.1).

Necrotizing enterocolitis of the newborn is characterized by varying degrees of mucosal necrosis.[5–8] This disorder occurs almost exclusively in premature infants, who typically demonstrate a sepsis-like illness with abdominal distention and, commonly, grossly bloody stools. Although many factors contribute to development of intestinal necrosis, a common pathway features ischemia, followed by disruption of the mucosal barrier, bacterial invasion, proliferation, and gas formation within the bowel wall.[5,6] Gram-negative bacteria of the normal flora may be important factors in triggering the injury process in a setting of a paucity of bacterial species and possible lack of protective gram-positive organisms.[7] Although outbreaks of necrotizing enterocolitis ascribed to single pathogens are described, prospective studies have failed to implicate a specific infectious cause in most cases (see Chapter 58).[8]

Antimicrobial-associated colitis is characterized by the presence of multiple yellow, plaque-like ulcerative lesions (1 to 5 mm) overlying erythematous, friable, colonic mucosa. In severe cases, lesions become confluent, resulting in sloughing of necrotic tissue and formation of the characteristic pseudomembrane.[9–11] Clinical manifestations of antimicrobial-associated colitis range from mild, watery diarrhea (with or without crampy abdominal pain) to fulminant colitis that can progress to toxic megacolon, colonic perforation, shock, and death. Overgrowth of toxigenic *Clostridium difficile* with release of potent cytotoxins is responsible for almost all cases.[9,10] *C. difficile*-associated colitis in the absence of antibiotic therapy is unusual; however, the use of both proton pump inhibitor and histamine H_2-receptor agonist drugs is associated with increased risk of community-associated *C. difficile*–associated disease.[11] The role of acid suppression in *C. difficile* infection is unclear.[12] Another high-risk group consists of patients who have inflammatory bowel disease.[13–16] It is unclear which risk factors play a major role, although it is hypothesized that the overall inflammatory state, immunosuppressive medications, poor nutritional status, and altered gastrointestinal flora are contributing factors.[17,18] Data suggest that the incidence and severity of *C. difficile*–associated disease are increasing in the US.[11,19] These increases may be associated with the emergence of newer strains with heightened virulence, antimicrobial resistance, or both. These "hypervirulent" strains, which carry variations in toxin genes and also are more resistant to the fluoroquinolones, erythromycin, and tetracycline, have emerged as a cause of *C. difficile*–associated disease outbreaks.[19–21] *C. difficile*-associated colitis is common in patients with human immunodeficiency virus (HIV) infection, in whom *C. difficile* can account for up to 54% of cases of bacterial diarrhea.[22] Even in the age of combination antiretroviral therapy, large bowel infections frequently are caused by opportunistic pathogens, such as cytomegalovirus (CMV), cryptosporidiosis, *Mycobacterium avium* complex, and spirochetosis.[23]

Noninfectious causes of inflammatory enteritis include ulcerative colitis, Crohn disease, Henoch-Schönlein purpura, eosinophilic gastroenteritis, enterocolitis complicating Hirschsprung disease, Behçet disease, and allergic colitis.[24,25] Intussusception can cause the onset of bloody, diarrheal stools, but inflammatory exudate is not expected.

Principal Etiologic Agents

Various infectious agents classically are considered causes of acute inflammatory enteritis (see Table 57.1). Patients come to medical attention with fever, abdominal pain, blood or mucus in stool, or a combination of these findings. However, many of these pathogens can cause clinical illnesses without overt characteristics of inflammation. The absence of clinical signs of inflammation therefore does not rule out these agents. In the US, most cases of inflammatory enteritis in children are caused by bacterial pathogens, whereas parasites are common among travelers to or indigenous populations of developing areas. Generally, differentiation among bacterial enteropathogens on clinical grounds alone is not possible; pathogenesis and potential complications associated with these agents are shown in Table 57.2. Detailed description can be found in pathogen-specific chapters.

TABLE 57.2

Pathogenesis and Complications of Principal Infectious Causes of Inflammatory Enteritis

Agent	Pathogenesis	Intestinal Complications	Extraintestinal Complications
Shigella spp. and enteroinvasive	Invasion of colonic enterocytes with lateral spread through	Colonic perforation,	Seizures, septicemia, HUS, immune-

Escherichia coli	mucosa and submucosa[110]; enterotoxins possibly involved[56]	protein-losing enteropathy	mediated disease (reactive arthritis, Reiter syndrome)
***Salmonella* spp.**	Invasion of distal ileal mucosa; can spread to reticuloendothelial system[111]	Colonic perforation (enteric fever), chronic carriage	Septicemia, meningitis, disseminated foci
Campylobacter jejuni* or *coli	Invasion of colonic enterocytes[112]	Chronic disease	Dissemination, immune-mediated disease (Guillain-Barré syndrome, reactive arthritis)
Yersinia enterocolitica	Invasion of ileal mucosa with inflammatory response; enterotoxins possibly involved[33,58]	Mesenteric adenitis	Dissemination with septicemia, suppurative foci
Enterohemorrhagic *E. coli*	Attaching and effacing lesions of colonic mucosa; production of Shiga-like toxins linked to HUS[46]	Toxic megacolon, colonic perforation	HUS, seizures
Clostridium difficile	Cytotoxin production	Toxic megacolon, colonic perforation	Septicemia
Entamoeba histolytica	Contact-dependent and contact-independent cytotoxicity; proteases; secretory factors possibly involved[43]	Chronic disease, toxic megacolon, colonic perforation	Ameboma, liver abscess, disseminated foci

HUS, hemolytic uremic syndrome.

Shigella Species.

All *Shigella* species can elicit prototypic acute bacillary dysentery, but *Shigella sonnei* most often causes uncomplicated watery diarrhea and is most prevalent in developed countries.[26,27] *Shigella* spp. have no known animal reservoir. Organisms are highly contagious and have a low infectious dose (as low as 10^2 colony-forming units), a feature hypothesized to be related to the organism's acid resistance.[28,29] Person-to-person and foodborne transmissions are most common in childhood shigellosis[27]; environmental contamination also can be a source of transmission.

Salmonella Species.

Nontyphoidal *Salmonella* serotypes cause a spectrum of illness that includes mild diarrhea, dysentery-like inflammatory enteritis, and disseminated disease, including septicemia and focal seeding (especially in immunocompromised hosts).[30] Most infections with

Salmonella in the US are foodborne,[31] most commonly through contaminated animal products such as unpasteurized milk, eggs, and improperly cooked meat. Enteric fever, caused by *Salmonella enterica* serovars Typhi, Paratyphi A, Paratyphi B, and Paratyphi C, can manifest with diarrhea or constipation.

Escherichia coli.

Diarrheagenic *Escherichia coli* organisms are divided into 5 major pathogenic categories on the basis of mechanism of pathogenesis.[32] Categories are (1) enterotoxigenic (watery diarrhea in infants and travelers), (2) enteroinvasive (dysentery identical to that caused by *S. sonnei*), (3) enteropathogenic (acute and chronic watery diarrhea in infants and children), (4) enterohemorrhagic or Shiga toxin–producing E. coli (hemorrhagic colitis associated with the hemolytic uremic syndrome), and (5) enteroaggregative (acute or persistent watery diarrhea prevalent in developing countries and in the immunocompromised host). Each type of *E. coli* except enterotoxigenic strains can cause inflammatory enteritis. Both enterohemorrhagic and enteroaggregative *E. coli* pathotypes occur commonly in the US.

Yersinia enterocolitica.

Yersinia enterocolitica typically causes acute diarrhea, fever, and abdominal pain.[33] Other manifestations include septicemia in infants and immunocompromised hosts, mesenteric lymphadenitis (mimicking appendicitis) in older children and young adults, dysentery, and postinfectious syndromes, including reactive arthritis, Reiter syndrome, glomerulonephritis, and erythema nodosum.[34,35] In the US, most *Y. enterocolitica* transmissions are foodborne, with outbreaks often caused by unpasteurized milk and contaminated pork or chitterlings.[36]

Campylobacter jejuni.

Campylobacter jejuni is one of the most commonly documented bacterial causes of diarrhea among people of all ages in the US and Canada.[37] Inflammatory enteritis and acute dysentery with severe abdominal pain and fever are common manifestations.[37] Bacteremia or dissemination is rare. The reservoir for *C. jejuni* is the gastrointestinal tract of wild and domestic birds and, to a lesser extent, other animals, thus allowing for foodborne outbreaks by ingestion of contaminated water, raw milk, or undercooked meat and poultry. Person-to-person spread has been documented; however, *C. jejuni* has a considerably higher ($10^{4–6}$ organisms) infectious dose and is less transmissible than *Shigella* spp.[37]

Aeromonas hydrophila.

Aeromonas species are found in soil and in fresh and brackish waters worldwide. *Aeromonas hydrophila* is associated with acute gastroenteritis, soft tissue infection, and bacteremia, especially in immunocompromised hosts. *A. hydrophila* is a significant cause of infection in the wake of natural disasters (hurricanes, tsunamis, and earthquakes) and has been linked to emerging illnesses, including prostatitis and hemolytic uremic syndrome.[38] Diarrhea caused by *A. hydrophila* also is associated with the consumption of seafood.[39] The mechanism of intestinal disease is unknown.

Vibrio parahaemolyticus.

Vibrio spp. other than *Vibrio cholerae* can elicit acute inflammatory enteritis with explosive, watery diarrhea. Illness usually is caused by *Vibrio parahaemolyticus* acquired through consumption of undercooked seafood.[40] Some non-O1 *V. cholerae* organisms also have been implicated in inflammatory enteritis.[41,42]

Entamoeba histolytica.

The classic clinical manifestation of *Entamoeba histolytica* enteritis is amebic dysentery, which can be acute and fulminant, especially in children, or mild and insidious with only abdominal pain, tenesmus, and small, frequent bowel movements.[43,44] Illness often follows an intermittent or waxing and waning course over weeks to months. Long incubation periods (1 week to 1 month) allow the onset of symptoms long after return from travel to a developing country where infection was acquired. Dissemination, most frequently to the liver, can occur after resolution of untreated amebic dysentery. Examination of the colonic mucosa of people with dysentery often reveals shallow, flask-like ulcers.[43] Trophozoites characteristically are found in stools of patients with dysentery or diarrhea; cysts more commonly are found in asymptomatic people.

Epidemiology

The epidemiology of infectious inflammatory enteritis is determined by the specific causative agent and the susceptibility of the host. Predictive epidemiologic associations should be explored in the patient's history, including foreign travel, childcare or institutional exposure, swimming and other exposure to water sources, receipt of antibiotics, diet, animal exposure, and underlying conditions. Risk factors and associated agents are shown in Table 57.3.

TABLE 57.3

Epidemiologic Risk Factors Associated With Infectious Agents of Inflammatory Enteritis

Risk Factor	Infectious Agents
Travel	Enterotoxigenic and enteroaggregative *Escherichia coli, Shigella, Salmonella, Campylobacter* spp., *Entamoeba histolytica*
Beef consumption	Enterohemorrhagic *E. coli, Salmonella*
Poultry consumption	*Salmonella, Campylobacter*
Pork consumption	*Yersinia enterocolitica, Salmonella* spp.
Seafood consumption	*Vibrio parahaemolyticus, Aeromonas hydrophila*
Water contamination	*Shigella, Salmonella, Campylobacter, Cryptosporidium* spp.
Institutional exposure or childcare	*Shigella, Cryptosporidium, Giardia lamblia,* enterohemorrhagic *E. coli*
Sexual transmission	*Treponema pallidum,* herpes simplex virus, *Neisseria gonorrhoeae, Chlamydia trachomatis, Shigella, E. histolytica*
Unpasteurized milk consumption	*Salmonella, Campylobacter, Y. enterocolitica, Mycobacterium* spp.
Antimicrobial therapy	*Clostridium difficile*

Infectious inflammatory enteritis often occurs in outbreaks related to person-to-person, foodborne, or waterborne transmission. The cause of outbreaks of enteric disease often can be predicted from the incubation period.[45] Cases with an onset between 1 and 16 hours of the source event usually are not inflammatory and are toxin mediated; those with an onset between 16 and 72 hours can be caused by infection, such as with *Salmonella* or *Shigella* spp., *C. jejuni,* enteroinvasive *E. coli, V. parahaemolyticus,* and *Y. enterocolitica;* an incubation period >72 hours suggests enterohemorrhagic *E. coli* O157:H7.[45,46] The implicated vehicle of transmission also can be helpful in predicting the cause. Cysts of parasites, including *Cryptosporidium parvum, Balantidium coli,* and *E. histolytica,* resist chlorination and thus contaminate municipal water supplies. Some pathogens are associated with specific foods, such as *Salmonella* spp. (undercooked poultry, produce, and eggs), *C. jejuni* (undercooked poultry), *V. parahaemolyticus* (raw and undercooked seafood), and *Y. enterocolitica* (pork, chitterlings, milk). *Neisseria gonorrhoeae,* herpes simplex virus, *Chlamydia trachomatis,* and *Treponema pallidum* are sexually transmitted agents of ulcerative proctitis in men who have sex with men, who also have an increased risk for colitis caused by typical enteric pathogens.

Pathogenesis

All inflammatory enteritides share common features of mucosal damage and accompanying release of inflammatory mediators. The mechanism of such damage elicited by infectious agents follows 1 of 2 general paradigms—cytotoxin elaboration or mucosal invasion, although some organisms are able to execute both mechanisms. The cytotoxic mechanism is exemplified by *C. difficile* colitis. Two *C. difficile* exotoxins (toxin A, a 308-kd enterotoxin, and toxin B, a 250- to 270-kd cytotoxin) damage enterocytes, thus leading to mucosal necrosis, and also may be responsible for secretion of fluid into the intestinal lumen.[47–49] Both toxins act by catalyzing glycosylation of Rho proteins (guanosine triphosphate-binding proteins) in target eukaryotic cells, thereby inducing derangement of the cytoskeleton and altering multiple cellular processes.

In addition, *C. difficile* toxins induce release of cytokines from epithelial cells, monocytes, macrophages, and neuronal cells of the lamina propria; these cytokines contribute to the toxin-mediated inflammation, apoptosis of colonocytes, and damage of colonic mucosa with formation of colonic ulcers and pseudomembranes.[10,50,51] A third potent toxin has also been described: a binary toxin named *C. difficile* transfer (CDT). CDT is not produced by all strains of *C. difficile*; disease caused by CDT-producing strains is associated with increased mortality. CDT is thought to disrupt the cellular cytoskeleton and increase adherence to the host cell.[52]

The invasive mechanism of bacterial enteritis is exemplified in shigellosis, yersiniosis, and salmonellosis. Pathogens penetrate the mucosa of the ileum and colon. The role of inflammation in these infections is not entirely clear, but apparently it is complex and may benefit both host and pathogen.[53] For example, experimental evidence suggests that migration of neutrophils into the intestinal lumen can exacerbate both *Shigella*- and *Salmonella*-associated diarrhea.[54,55] Moreover, mice deficient in the apoptotic (and proinflammatory) enzyme caspase 1 are resistant to *Salmonella* infection. However, mice deficient in certain cytokine responses also are unable to limit *Salmonella* infection to the intestine and are more likely to die of systemic disease. Much is known about the molecular events underlying *Salmonella* pathogenesis.[56] The clinical manifestations of inflammatory enteritis may be the result of a finely tuned coevolution between host and parasite, the result of which favors the survival of both. In addition, invasive pathogens can secrete enterotoxins.[56–59] A summary of pathogenic mechanisms for principal pathogens is shown in Table 57.2.

Diagnostic Evaluation

Before embarking on a diagnostic evaluation of a patient with enteric disease, one should consider whether determining the causative agent will affect management. Most gastrointestinal tract infections in the US are caused by viruses, for which no specific therapy exists. Most viral infections do not elicit an inflammatory syndrome, and therefore the presence of acute inflammatory enteritis suggests a bacterial or parasitic origin. Some bacterial agents of inflammatory enteritis can be treated to benefit the patient, potential contacts, or both, whereas others (e.g., nontyphoid *Salmonella* confined to the gut) are not responsive to antimicrobial therapy. A practical, selective diagnostic approach to the patient with enteritis should be cost-effective and likely to yield information helpful for management.

By far the most common infectious causes of acute inflammatory enteritis in US children are the bacterial enteropathogens. Relevant epidemiologic factors (see Table 57.3), disease patterns in the community, and patient-related characteristics are useful in assessing the likelihood of a bacterial cause.[60–62] Suggestive signs and symptoms include fever, abrupt onset of diarrhea, >4 stools per day, absence of vomiting before the onset of diarrhea, and presence of blood or mucus in stool. The patient with none of these features is unlikely to have a bacterial pathogen. A scoring system for predicting bacterial enteritis has been proposed, in which risk is weighted for each feature.[61] However, such a quantitative approach is unlikely to determine the precise risk of inflammatory enteritis in all locales.

The leukocyte assay of stool mucus is a practical, inexpensive screening test that can be used to predict probable inflammatory enteritis, thereby helping to limit performance of stool culture.[60,63,64] The sensitivity and specificity of this test in predicting bacterial enteritis have been reported to be >80% (for ≥5 white blood cells/high-power field)[60]; however, the reported values vary widely among studies, in part reflecting differences in the definition of a positive result. Moreover, the predictive value of the assay depends on the likelihood of bacterial inflammatory enteritis as indicated by historical factors and clinical signs. Most leukocytes detected in stool are neutrophils (mononuclear cells also can be associated with *Salmonella* infection).[64] The presence of leukocytes is not always indicative of bacterial inflammatory enteritis (Table 57.4), given that leukocytes can be present in inflammatory bowel diseases such as ulcerative colitis and Crohn disease, and fecal neutrophils occasionally can be present in cases of viral enteritis.[65]

TABLE 57.4

Association of Fecal Leukocytes With Intestinal Pathogens

Present	Variable	Absent
Campylobacter Enteroinvasive *Escherichia coli* *Shigella*	*Clostridium difficile*	*Bacillus cereus*
	Salmonella	*Clostridium perfringens*
	Schistosoma	*Entamoeba histolytica*
	Vibrio parahaemolyticus	Enteric viruses
	Yersinia enterocolitica	Enteropathogenic *E. coli*
		Enterotoxigenic *E. coli*
		Giardia intestinalis
		Vibrio cholerae

Fecal lactoferrin, detected with a commercially available rapid agglutination test, correlates closely with the presence of fecal leukocytes.[66] In one study, 94% (16 of 17) of patients whose smears of fecal mucus had >1 neutrophil/high-power field also had a positive lactoferrin test result, whereas 16% (3 of 19) of patients with diarrhea without neutrophils in smears and none of 7 healthy controls had positive test results. In another study, the fecal lactoferrin test had a better positive predictive value than did the fecal leukocyte smear or occult fecal blood detection for the detection of bacterial pathogens.[67] Lactoferrin is stable in fecal specimens and can be detected even when leukocytes disintegrate during transport or storage. Fecal lactoferrin tests can have false-positive results in infants who are breastfed. Fecal calprotectin, an early predictor of acute bacterial versus viral gastroenteritis, is another valuable noninvasive marker in young children, with a diagnostic accuracy of 92%. In one study, combined fecal calprotectin and serum C-reactive protein tests improved diagnostic accuracy to 94% for acute bacterial gastroenteritis.[68]

Selection of Tests to Confirm Cause

When performance of stool culture is indicated on the basis of history, physical examination, or fecal leukocyte assay, specimens should be inoculated into culture medium adequate for recovery of *Shigella, Salmonella, Y. enterocolitica,* and *C. jejuni.* In the US, the Centers for Disease Control and Prevention recommends that detection of Shiga toxin–-producing *E. coli* should be attempted regardless of age, seasonality, and the presence or absence of blood in stool.[69] If a history of seafood ingestion or exposure to brackish water is elicited, specialized media should be requested for isolation of *Vibrio, Aeromonas,* and *Plesiomonas* spp. Other specialized tests are sometimes indicated in the evaluation of patients with diarrhea. Preferred diagnostic methods for etiologic agents of inflammatory enteritis are shown in Table 57.5 (see Chapter 286).

TABLE 57.5

Diagnostic Studies for Enteropathogens

Organism	Diagnostic Studies
ACUTE DISEASE	
Balantidium coli	Examination of stool or mucosal scrapings (sigmoidoscopy) for trophozoites or cysts
Campylobacter	Stool culture (selective media and incubation conditions); antigen detection by EIAs for *C. jejuni* and *Escherichia coli* (variable performance); multiplex PCR-based assays[a]
Cryptosporidium	Modified acid-fast or auramine or fluorescein-labeled monoclonal antibody stain of stool, duodenal aspirate, or small bowel biopsy specimen; antigen detection by EIA or immune chromatographic tests

Entamoeba histolytica	Examination of stool, biopsy or mucosal scrapings (proctosigmoidoscopy) for trophozoites or cysts; antibody detection by EIA on serum in invasive disease
Escherichia coli	Stool culture on sorbitol-MacConkey agar for detection of O157 STEC strains for further testing; immunoassay to detect non-O157 STEC; multiplex PCR assays that can detect STEC, enterotoxigenic *E. coli*, enteropathogenic *E. coli* enteroaggregative *E. coli* and enteroinvasive *E. coli*[a]
Salmonella	Stool culture (enteritis; see Chapter 146 for diagnostic testing in enteric fever and invasive infections); multiplex PCR assays[a]
Schistosoma	Detection of eggs on microscopic examination of stool and rectal mucosal biopsy
Shigella	Stool culture; multiplex PCR assays[a]
Yersinia enterocolitica	Stool culture, blood culture, culture of specimen from other body sites (e.g., mesenteric lymph nodes, peritoneal fluid, synovial fluid); see Chapter 148)
Cytomegalovirus	Endoscopic mucosal biopsy for microscopy (viral inclusions), immunochemical staining, shell-viral culture, pp65 antigen
CHRONIC DISEASE	
Candida	Potassium hydroxide stain; stool culture
Enteroaggregative *E. coli*	Stool culture; DNA probe; adherence to human laryngeal cell line (HEp-2)
Mycobacterium	Acid-fast examination and mycobacterial culture of biopsy specimens
PROCTITIS	
Chlamydia trachomatis	Culture; NAAT (limited data in this setting)
Herpes simplex	Culture; enzyme immunoassay or direct fluorescent antibody test
Neisseria gonorrhoeae	Culture; NAAT
Treponema pallidum	Dark-field microscopy examination of mucosal scrapings; serology
Entamoeba histolytica	Microscopic examination of stool or intestinal biopsy tissue; serology
OTHER	
Antimicrobial-associated colitis	Toxin assays, sigmoidoscopy with rectal biopsy
Necrotizing enterocolitis	Abdominal radiograph

[a] Several commercially available multiplex PCR assays that are licensed by the Food and Drug Administration provide simultaneous detection of multiple enteropathogens. Although data on test performance are available, these tests need clarification of significance of multiple enteropathogen detections before wide implementation.[113]

EIA, enzyme immunoassay; NAAT, nucleic acid amplification test; PCR, polymerase chain reaction; STEC, Shiga toxin–producing *Escherichia coli.*

Direct microscopic examination of stool specimens can reveal the following: protozoal trophozoites, cysts, or oocysts; fungal spores; or helminthic larvae. Although parasitic diseases are not as common in the US as elsewhere and rarely cause inflammatory enteritis, their presence should be suspected, and direct examination for parasites should be performed, in the following high-risk situations: (1) recent travel to a developing country, (2) persistent diarrhea (>14 days), (3) immunocompromised status, (4) contact with a person with intestinal parasitic disease, and (5) occurrence of diarrhea in the presence of an outbreak of undetermined cause. Eosinophilia in a patient with inflammatory enteritis may indicate strongyloidiasis.[70] If amebic dysentery is suspected on the basis of risk factors, at least 3 fresh stool specimens should be examined using the iodine-trichrome method. Yield can be increased by examining stool concentrates stained with iron-hematoxylin.[43] The diagnosis is made visually by detection of hematophagous trophozoites or characteristic cysts in stools. Serum antibody to *E. histolytica* is present in 85% to 95% of patients with invasive disease but is likely to be absent in asymptomatic cyst excreters and persons with mild diarrhea.[43]

Intestinal biopsy (for histologic examination, special staining for microscopic identification of pathogen, and culture) should be considered in patients with persistent inflammatory enteritis or in an immunocompromised host when the diagnosis cannot be made by noninvasive methods. Specimens obtained at biopsy generally have better yield for parasites such as *E. histolytica.* Certain entities, such as enteropathogenic *E. coli,* exhibit characteristic histopathologic features on electron microscopy.

Several tests are available for diagnosis of *C. difficile* disease using targets for toxin (enzyme immunoassay [EIA]), toxin gene (nucleic acid amplification test), glutamate dehydrogenase or organism dehydrogenase (GDH-EIA), and isolation (culture). The optimal testing method remains an area of controversy.[71] Culture-based methods are resource intensive and not widely used. Toxin EIA has suboptimal sensitivity and specifically, and Infectious Diseases Society of America and Society for Healthcare Epidemiology of America guidelines for adults discourage use as a single test.[72] Nucleic acid amplification tests have higher sensitivity but are more costly, and tests detect the gene that encodes toxin and not the toxin itself; thus, a positive test result may represent colonization.[73] Algorithmic approaches have gained popularity. A common 2-step approach consists of GDH and toxin EIA testing, followed by confirmatory testing with nucleic acid amplification testing for specimens with discrepant findings.[74]

Inflammatory Enteritis in the

Immunocompromised Host

Clinical Approach

Diarrhea is a symptom in up to 50% to 60% of patients with the acquired immunodeficiency syndrome (AIDS) in the US.[22,75] Although hospital admissions attributable to diarrhea have declined, diarrhea still is a debilitating symptom in patients infected with HIV, even in the era of combination antiretroviral therapy.[22,23,76,77] Digestive tract disease in children with AIDS and other immunodeficiencies can be produced by a variety of infectious agents, including HIV.[22,23,75,78–80] Depending on the specific pathogen and the immunologic status of the patient, clinical manifestations can be acute or chronic. Patients with $CD4^+$ T-lymphocyte counts <50 cells/mm^3 and low serum albumin levels are more likely to have an infectious cause of digestive tract disease.[81] Signs and symptoms include diarrhea, vomiting, anorexia, failure to thrive, weight loss, and malabsorption. Histopathologic abnormalities in immunocompromised patients usually are similar to changes in healthy patients, although the changes often are more severe. In addition to typical enteric pathogens, opportunistic agents cause acute and chronic inflammatory enteritis in immunocompromised patients; disease caused by the following agents fulfills the AIDS-defining criteria of the Centers for Disease Control and Prevention: *Candida, Cryptosporidium, Histoplasma, Cystisospora* (formerly *Isospora*) spp., *M. avium* complex, *Salmonella* infection with septicemia, CMV, and herpes simplex virus.[22,75,76]

In early studies, no infectious cause of enteric disease was found in a large proportion of patients with AIDS. Subsequent studies demonstrated that aggressive evaluation, including endoscopy with biopsy, substantially improved diagnostic yield.[79,80] These data, coupled with the broad range of pathogens seen in the HIV-infected population (even in the era of combination antiretroviral therapy), support an intensive diagnostic approach when reasonable empiric therapy fails.[82]

Typhlitis (necrotizing enterocolitis of the cecum and surrounding tissues) is a life-threatening condition that occurs in profoundly neutropenic patients, usually people undergoing aggressive chemotherapy (with or without radiation) for malignant disease.[83]

Typhlitis also can occur in people with AIDS.[76] Typhlitis manifests as fever, abdominal pain, tenderness (especially right-sided, lower-quadrant tenderness mimicking that of acute appendicitis), and diarrhea. Evidence of right-sided colonic inflammation can be obtained using computed tomography, ultrasonography, and plain radiography.[83]

An approach to evaluation of the immunocompromised host with inflammatory enteritis is summarized in Box 57.1.

Box 57.1

Diagnostic Evaluation of Immunocompromised Patients With Inflammatory Enteritis

1. Routine stool culture for *Shigella, Salmonella,* and *Campylobacter jejuni* or *coli*
2. Specialized stool culture for *Mycobacterium avium* complex, other *Campylobacter* spp., *Yersinia enterocolitica, Escherichia coli*
3. Assay for *Clostridium difficile* toxin
4. Microscopic stool examination:
    a. Fecal leukocytes or fecal lactoferrin test for assessment of invasive bacterial cause
    b. Ova, cysts, and parasites such as *Giardia intestinalis, Strongyloides, Entamoeba histolytica* (see Table 57.1)
    c. Acid-fast stain for *Mycobacterium, Cryptosporidium, Cyclospora, Isospora*
5. Blood culture for bacteria, mycobacteria, detection of cytomegalovirus
6. If symptoms persist, if results of the preceding workup are negative, or if the patient is severely ill:

a. Obtain abdominal radiographs to detect pneumatosis intestinalis (present in severe cytomegalovirus colitis).

b. Consider esophagogastroduodenoscopy or colonoscopy with intestinal biopsy for histologic examination, culture, special stains, and molecular diagnosis.

Specific Agents

Cytomegalovirus.

Gastrointestinal tract disease caused by CMV occurs almost exclusively in the setting of immunodeficiency (including AIDS), organ transplantation, cancer chemotherapy, and corticosteroid therapy.[84–87] Colitis, the most common manifestation of enteric CMV disease, is characterized by fever, diarrhea, abdominal pain, and hematochezia. Abdominal radiographs can reveal pneumatosis intestinalis or free peritoneal air.[78] Endoscopic findings in patients with CMV-associated inflammatory colitis range from localized hyperemia to deep ulceration with overlying exudate and necrosis; the most common finding is mild, patchy colitis. If CMV is suspected, biopsy should be performed even if the mucosa appears normal grossly. Pp65 antigen detection and CMV DNA detection with polymerase chain reaction technology aid the diagnosis.[87,88] Complications of CMV-associated colitis include intestinal perforation, severe hemorrhage, peritonitis, small bowel obstruction, and toxic megacolon. Ganciclovir therapy has been shown to be beneficial for CMV-associated colitis when treatment is initiated early in the disease.[84,87] Ganciclovir induction therapy should be administered for 3 to 6 weeks, depending on the degree of involvement and immunologic state of the patient; maintenance therapy may be required thereafter.[88]

Cryptosporidium.

Cryptosporidial infection, one of the most common causes of enteric disease in patients with AIDS, occurs in 10% to 20% of adults with AIDS in the US.[89,90] This infection may be less common in children and has been decreasing in frequency in the age of antiretroviral therapy.[91] Typical AIDS-related diarrheal syndromes consist of profuse, watery, and often bloody diarrhea associated with anorexia and weight loss; death is common.

Mycobacterium avium Complex.

M. avium complex infections are common in patients with AIDS and low CD4$^+$ T-lymphocyte counts.[92] Signs and symptoms usually are nonspecific and include fever, night sweats, malaise, and diarrhea. The small intestine appears to be involved more commonly than the colon. Mucosal changes include erythema, edema, friability, and, occasionally, small erosions and fine white nodules.

Fungi.

Local or systemic fungal infections can cause chronic inflammatory enteritis.[93,94] Fungal pathogens include the following: *Candida* spp., which can cause chronic, bloody, or nonbloody diarrhea; *Paracoccidioides brasiliensis* (South American blastomycosis), which causes a granulomatous or ulcerative lesion in the gastrointestinal tract; *Histoplasma capsulatum,* which can manifest with ulceration, bleeding, or obstruction; and the phycomycoses, which can cause abdominal pain, diarrhea, gastrointestinal tract bleeding, and peritonitis.

Management

Fluid loss is the most important consequence of acute gastroenteritis. The primary aims of management are aggressive rehydration and replacement of electrolytes by oral or intravenous routes, maintenance of blood volume and acid-base balance, and replacement of ongoing diarrheal losses. Nutritional support also is important, especially in immunocompromised and malnourished patients, who are prone to persistent illness. Early feeding minimizes caloric deficit and stimulates repair of the intestinal brush border.[95] Breastfeeding of infants should be continued, especially in developing countries, thus adding the benefit of passively acquired protective factors. In severe persistent inflammatory enteritis in which absorption is compromised, parenteral nutrition is considered.

Antimicrobial therapy is reserved for the small proportion of patients with suspected or proven bacterial causes of diarrhea in whom benefit is likely.[45] Empiric antibiotic therapy is appropriate in the following patients with inflammatory enteritis: (1) severely ill patients with strongly suspected bacterial dysentery; (2) immunocompromised people, including patients with AIDS and recipients of immunosuppressive drugs; (3) infants <3 months of age with *Salmonella* infection (who are at high risk of bloodstream infection [BSI]); (4) patients with hemoglobinopathy or asplenia; and (5) people with a high likelihood of a treatable cause according to history, physical findings, or epidemiologic factors. Antibiotics are not recommended in patients with suspected Shiga toxin–producing *E. coli* infection (these patients typically present afebrile with bloody diarrhea) because such therapy may increase the risk of hemolytic-uremic syndrome,[96] although this is controversial.[97]

Antibiotics hasten clinical improvement in people with shigellosis and severe *Campylobacter*-associated enteritis if treatment is given early in the course.[97] Therapy also shortens the duration of fecal shedding of these organisms and of *Y. enterocolitica* infection. In developed countries, trimethoprim-sulfamethoxazole has long been effective empiric treatment for suspected shigellosis in children. However, increasing antibiotic resistance renders this agent ineffective in many cases. Antibiotic susceptibility testing should be performed on patient isolates, and clinicians should be aware of susceptibility patterns in their area. Cefixime has in vitro activity against most strains of *Shigella* that are resistant to ampicillin or trimethoprim-sulfamethoxazole and is safe for use in children.[98] One dose of ciprofloxacin usually is adequate for treatment of all *Shigella* species except *Shigella dysenteriae* 1; however, use of fluoroquinolones in children should be restricted. Additionally, fluoroquinolones are a risk for *C. difficile* infection. A Scientific Working Group of the World Health Organization raised the possibility that the efficacy of fluoroquinolones for shigellosis may outweigh the small risk of adverse effects in selected children.[99] The role of antibiotics in treating people with specific causes of bacterial gastroenteritis is summarized in Table 57.6.

TABLE 57.6

Use of Antimicrobial Therapy in Inflammatory Enteritis

Antimicrobial Therapy	Enteropathogens
Effective clinically	*Shigella,* enteroinvasive *Escherichia coli*
Decreased excretion	*Shigella,* enteroinvasive *E. coli, Yersinia enterocolitica, Campylobacter jejuni*
Indicated in certain hosts[a]	*Salmonella, Campylobacter,* enteropathogenic *E. coli,* enterotoxigenic *E. coli, Clostridium difficile, Yersinia enterocolitica*
Unclear effect	Enteroaggregative *E. coli, Aeromonas,* noncholera *Vibrio* spp.
Controversial[b]	Enterohemorrhagic *E. coli*

[a] Antimicrobial agents warranted for patients with severe colitis or with increased risk of disseminated disease: infants <3 months of age, persons with immunodeficiency disorders (including acquired immunodeficiency syndrome, hemoglobinopathy, and asplenia), and recipients of immunosuppressive drugs.

[b] See Chapter 137 and text.

Nonspecific therapies other than antimicrobial agents are available for symptomatic treatment of patients with diarrhea. Bismuth subsalicylate has some effect in decreasing stool volume and illness in traveler's diarrhea.[100] One study showed a decrease in frequency and volume of diarrhea in children.[101] Antiperistaltic agents (loperamide and diphenoxylate hydrochloride) and antiemetic agents can be effective in the management of diarrhea in adults; however, their use is not recommended in infants and young children because safety and efficacy data are lacking.[102] Antiperistaltic agents have been demonstrated to worsen the clinical course of disease caused by *Shigella* spp., *C. difficile,* and *E. coli* O157:H7. Fecal microbiota transplantation has demonstrated promising results in adults for treatment of relapsing *C. difficile* infections. Patients appear to have immediate improvement of diarrhea after a fecal microbiota transplantation procedure and usually are symptom-free for several months. The ideal protocol for screening potential donors and the optimal mode of transplantation remain unclear. Methods of transplantation have advantages and disadvantages. Transplantation by nasogastric tube, upper endoscopy, nasoduodenal or nasojejunal tube, colonoscopy, and enema has shown similar results. The opinion of some experts is that transplantation directly into the colon is most physiologic; however, active infection also carries a risk of perforation.[103,104] Transplantation in the proximal gastrointestinal tract carries less risk for perforation, although concern exists regarding aspiration or potential degradation from gastric and pancreaticobiliary secretions.[105,106]

Infants With Inflammatory Enteritis

An infant <3 months of age with inflammatory enteritis should be managed cautiously because of the propensity of *Salmonella* strains to cause BSI with disseminated suppurative foci in this age group.[107,108] Although the precise frequency of BSI is not known, a prospective study of children with gastroenteritis caused by *Salmonella* spp. reported BSI in 6 of 91 patients (2 of the 6 infants were ≤3 months of age).[108] Infants whose condition appears toxic and who have diarrhea as the prominent feature of illness should be hospitalized, cultures of blood and cerebrospinal fluid should be obtained, and intravenous antibiotics with a spectrum of activity against enteric pathogens, as well as common invasive pathogens, should be given. In the infant ≤3 months of age whose condition does not appear toxic, one panel of experts recommended obtaining blood and stool cultures if the stool contains blood or leukocytes.[108] Cefotaxime or ceftriaxone is effective for treatment of invasive focal *Salmonella* infections.[109] If stools contain blood or leukocytes, empiric antimicrobial therapy may be initiated. The value of antimicrobial therapy for *Salmonella* gastroenteritis without BSI has not been established. No evidence of clinical benefit of antimicrobial therapy exists in otherwise healthy children and adults with nonsevere *Salmonella* diarrhea.

Necrotizing Enterocolitis

Kanecia Zimmerman, Daniel K. Benjamin Jr.

Necrotizing enterocolitis (NEC) is the most common neonatal gastrointestinal emergency. NEC results in substantial morbidity and mortality, particularly in premature infants. Although no significant improvements in morbidity and mortality rates have been made in recent years, our understanding of the pathogenesis of NEC continues to improve. Incomplete gastrointestinal development, underlying gastrointestinal pathologic features, and bacterial translocation likely all have roles in the development of NEC. Further advancement of knowledge about the interaction of these factors in the development of NEC may lead to more effective prevention and management, thereby improving the duration and quality of life for many premature infants.

Epidemiology

NEC affects predominantly premature infants, and its incidence has not significantly changed in recent years. According to studies conducted by the Canadian Neonatal Network and the National Institute of Child Health and Human Development Neonatal Research Network, NEC affects approximately 5% of infants <33 weeks of gestation and 11% of infants ≤28 weeks of gestation.[1,2] NEC has no seasonal, geographic, or sex predilection.[3,4] Among infants with less than 1000 g birth weight, NEC usually develops after the first 2 weeks of life; among more mature and full-term infants, NEC may occur as early as the first week of life.[1,5–7]

Risk factors for NEC in full-term infants suggest that mucosal injury and ischemia are important (Table 58.1).[5–7] In a multicenter review of 30 term and near-term infants, these infants were more likely to develop NEC if they had congenital heart disease, polycythemia, or documented early-onset sepsis.[8] Although cyanotic congenital heart disease is a risk factor for NEC among full-term infants, the overall incidence in this population is low. In an analysis of nearly 7000 full-term infants with ductal-dependent congenital heart disease, NEC occurred in 21 (0.3%); only 12 of these infants were less than 37 weeks of gestational age.[9]

TABLE 58.1

Factors and Conditions Associated With Necrotizing Enterocolitis

Premature Infant	Full-Term Infant
Lower gestational age	Cyanotic congenital heart disease
Feeding	Polycythemia
Histamine H_2-blocking agents	Exchange transfusion
Empiric antibiotics	Perinatal asphyxia
	Small for gestational age or intrauterine growth restriction
	Umbilical catheter
	Maternal pre-eclampsia
	Antenatal cocaine
	Premature rupture of membranes
	Milk allergy
	Gestational diabetes

Pathologic Findings and Pathogenesis

Pathologic lesions of NEC occur throughout the intestine, but the most common sites in preterm infants are the watershed areas of the intestine including the distal ileum and proximal colon.[10] Initial lesions manifest as superficial mucosal ulceration, submucosal hemorrhage, and edema.[11] Apoptosis or necrosis of intestinal epithelia contribute to loss of intestinal epithelia, and this loss of mucosal barrier function may allow passage of bacteria and undigested food antigens into the submucosa and initiation of inflammatory processes.[12,13] In severe cases, coagulative transmural necrosis and perforation occur. If the disease does not progress to this stage, healing can occur by epithelialization and proliferation of fibroblasts and granulation tissue. Strictures can follow, and their occurrence can be independent of NEC severity.[14–16]

Although the pathologic findings in NEC provide some insight into its pathogenesis, the physiologic processes associated with the disease are not completely understood. Clinical NEC is likely the "final common pathway" of multiple interactions of immaturity, injury, bacteria, and substrate (Box 58.1).[10,11,17] Intestinal immaturity is characterized functionally by poor motility, weak barrier function, incomplete immune defenses, and limitations in digestion and absorption.[13,18,19] The high incidence of NEC after initiation of enteral feedings (90% of NEC cases) suggests an interaction between substrate and intestinal immaturity that contributes to the development of the disease.[20]

Box 58.1

Limitations of the Preterm Infant's Intestine That May Contribute to Risk of Necrotizing Enterocolitis

Immunologic Factors

Decreased secretory immunoglobulin A

Decreased intestinal lymphocytes

Poor antibody response

Innate immune system immaturity

Luminal Factors

Lower hydrogen ion output in stomach

Lower proteolytic enzyme activity

Immature Intestinal Barrier

Less protective mucin barrier

Less protective microvillous membrane

Higher permeability

Lower or Less Organized Motility

Most investigators believe that intestinal injury caused by major perinatal hypoxic-ischemic events is not likely to contribute directly to NEC pathogenesis in preterm infants. However, hypoxia and ischemia lead to increased production of nitric oxide and endothelin. These molecules help regulate vascular tone and likely have a downstream role in NEC pathogenesis.[19,21]

Unlike hypoxic-ischemic events, processes that allow microbial invasion of the intestinal epithelia and submucosa likely have direct effects on the pathogenesis of NEC. The immature epithelium of a newborn infant is unable to adapt its immune function in response to the increased microbial exposure that occurs during intestinal colonization. Ideally, innate immunity factors balance proinflammatory functions that prevent bacterial overgrowth and invasion, with anti-inflammatory functions. The inability of the immature epithelium to balance these opposing factors leads to weakening of barrier function and intestinal cell apoptosis.[13,22]

The premature infant's increased expression of the proinflammatory mediator toll-like receptor 4 (TLR4) and decreased expression of the inflammatory regulator IκB, compared with adults, may provide some basis for the excessive inflammatory response that leads to NEC.[19,23,24] TLR4 is located on intestinal cell surfaces and signals synthesis of proinflammatory mediators in response to the bacterial cell wall component lipopolysaccharide. IκB regulates the proinflammatory transcription factor nuclear factor κB (NF-κB).

The inflammatory processes that lead to NEC suggest that the existence of microbial colonization is an important inciting event. However, epidemiologic observations suggest that the composition of microbial colonization may also be important. NEC has been associated with prolonged exposure to antibiotics and antacids, 2 therapeutic drug classes that are likely to modify the extent and composition of microbial colonization.[25,26] Moreover, multiple bacteria known to colonize the intestines have been associated with

NEC: bacteria with known toxins (e.g., hemolysins of staphylococci, enterotoxins of *Escherichia coli,* and clostridia toxins), and other gram-negative bacteria. These bacteria are thought to be responsible for the pathognomonic hepatobiliary gas or intramural gas (pneumatosis intestinalis; Fig. 58.1) produced during invasion of the intestinal submucosa.[27–29]

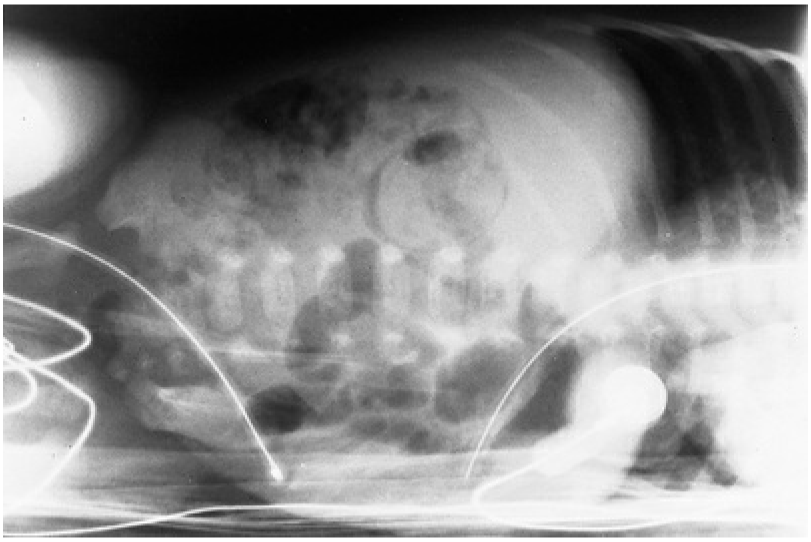

FIGURE 58.1 Abdominal radiograph of an infant with necrotizing enterocolitis and pneumatosis intestinalis. (From Willoughby RE Jr, Pickering LK. Necrotizing enterocolitis and infection. Clin Perinatol 1994;21:307–315.)

Notably, molecular methods to characterize intestinal flora in preterm babies with and without NEC have failed to identify consistent bacterial pathogens.[30–32] This finding and the observation that organisms implicated in NEC are found in symptomatic and asymptomatic infants further support the complexity of NEC pathogenesis and the low likelihood that infectious etiologic agents are solely responsible. However, infectious causes may be the final defining factor in some cases; NEC outbreaks have been associated with illness in caregivers, and viruses (e.g., rotavirus and cytomegalovirus) have been implicated in clusters of NEC cases.[33–38]

Clinical Manifestations, Differential Diagnosis, and Clinical Approach

Although progress has been made in understanding the mechanisms of the pathogenesis of NEC, diagnostic and therapeutic approaches have not advanced. The clinical course of NEC can vary from a slow, indolent process to one that is fulminant with lethal progression over hours. Classic signs include abdominal distention with discoloration or erythema of the overlying skin and bloody stools. NEC also may occur in the absence of these signs, especially in the most premature infants.[36] Many infants have less specific signs indicative of generalized sepsis (Box 58.2). Thrombocytopenia and low or high white blood cell counts are common. The combination of systemic hypotension, falling leukocyte and platelet counts, and worsening metabolic acidosis suggests worsening disease.[19] These signs may reflect the bloodstream or peritoneal infection that occurs in approximately 30% of preterm infants with advanced NEC. Intestinal bacterial flora organisms, specifically including gram-negative organisms, are most often isolated.[39,40]

Box 58.2

Initial Signs of Necrotizing Enterocolitis

Feeding intolerance (decreased oral intake, vomiting, increased gastric residual fluid)

Lethargy

Temperature instability

Apnea

Metabolic acidosis

Shock

Disseminated intravascular coagulation

Ileus

Clinitest[a]-positive stools

Heme-positive stools or heme-positive vomitus

---

[a] Proprietary (Bayer) alkaline copper sulfate reagent test.

Differential diagnoses include medical conditions associated with decreased intestinal motility: bacterial or viral infections, metabolic disorders such as hypothyroidism, and congenital heart disease. NEC is suspected when gastrointestinal signs predominate. Infectious enterocolitis, small bowel volvulus, colonic aganglionosis with enterocolitis, focal intestinal perforation (FIP), and other surgical diseases of the intestinal tract also should be considered.[19,36]

Of all possible differential diagnoses, FIP is potentially most difficult to distinguish from NEC. NEC and FIP have similar predilection for the distal ileum and may have similar outcomes. The age of disease onset is different. FIP usually occurs in the first few postnatal days in extremely low–birth weight (<1000 g at birth) infants, whereas NEC in the most premature infants occurs beyond the first 2 postnatal weeks.[41,42] FIP is more commonly associated with *Candida* and staphylococcal peritonitis, whereas positive peritoneal cultures in NEC are more likely the result of Enterobacteriaceae.[40]

Once the diagnosis of NEC is suspected, confirmation of the disease depends on radiographic findings (see Fig. 58.1). Pneumatosis intestinalis can be subtle, but it is pathognomonic. Thickened and dilated loops of small bowel are common but nonspecific. Pneumoperitoneum (best assessed on a cross-table or left lateral decubitus radiograph) or intra-abdominal fluid suggests the need for surgical intervention. Diagnostic criteria for NEC were originally developed by Bell and Conorkers. Modified criteria provide uniformity for therapeutic decision making (Table 58.2).[43]

TABLE 58.2

Modified Bell Staging for Necrotizing Enterocolitis

Stage	Classification	Systemic Signs	Intestinal Signs	Radiograph
IA	Suspected NEC	Temperature instability, apnea, bradycardia, lethargy	Increased pregavage residuals, midabdominal distention, emesis, heme-positive stool	Normal or intestinal dilation, ileus
IB	Suspected NEC	Same as above	Bright red blood from rectum	Same as above
IIA	Proven NEC: mildly ill	Same as above	Same as above, plus absent bowel sounds, with or without abdominal wall tenderness	Intestinal dilation, ileus, pneumatosis intestinalis

IIB	Proven NEC: moderately ill	Same as above, plus mild metabolic acidosis and mild thrombocytopenia	Same as above plus absent bowel sounds, definite tenderness, with or without abdominal cellulitis or right lower quadrant mass	Same as stage IIA plus definite ascites
IIIA	Advanced NEC: severely ill, bowel intact	Same as stage IIB, plus hypotension, bradycardia, severe apnea, combined respiratory and metabolic acidosis, disseminated intravascular coagulation, and neutropenia	Same as above plus signs of generalized peritonitis, marked tenderness, and distention of the abdomen	Same as stage IIA plus definite ascites
IIIB	Advanced NEC: severely ill, bowel perforated	Same as stage IIIA	Same as stage IIIA	Same as stage IIB plus pneumoperitoneum

Some researchers have investigated early indicators of NEC that may prompt early intervention and potentially decrease morbidity and mortality. Among these indicators, increases in the following biomarkers have been associated with NEC: exhaled breath hydrogen, serum levels of interleukin-6, endotoxin, α_1-antitrypsin, stool-reducing substances and specific short-chain fatty acid profiles, neutrophil CD64, and C-reactive protein (CRP). Investigators also have evaluated the utility of ultrasound examination to diagnose early NEC. When compared with plain radiographs, ultrasound examination may be able to identify a wider array of pathologic findings in the early stages of NEC. Neither ultrasound study nor biomarker determination has been introduced into clinical practice.[44–48]

Management

Management of NEC is largely supportive and is directed at preventing progression, restoring homeostasis, and minimizing complications. Providers should withhold oral feedings and decompress the stomach through placement of a large-bore nasogastric tube and application of intermittent suction. Intravenous access is required to provide fluid, electrolytes, nutrition, and antimicrobial agents. The duration of enteral feeding restriction depends on radiographic findings, clinical status, and local practice. Many patients whose signs resolve and whose NEC does not progress beyond stage I (Table 58.2) are fed after 48 to 72 hours. If the period of enteral restriction is longer (e.g., >7 days, common if ≥stage II), total parenteral nutrition should be considered. Infants are initially fed low volumes of elemental formula or breast milk. This strategy allows optimal nutrient absorption and avoids osmolar challenge and further injury to the intestinal mucosa.[49]

Few randomized clinical trials have been performed to guide feeding strategies after NEC.[49] Among such studies, however, serial CRP levels in the days following NEC diagnosis appeared to be useful. When less severe disease was observed, and radiographs normalized, CRP was persistently low. These infants were safely fed earlier and antibiotics were stopped sooner (48 hours if cultures were negative) than in infants whose CRP levels remained elevated. Abnormal CRP values in infants with stage II NEC returned to normal at a mean of 9 days from onset, except in 7 infants, all of whom required exploratory operations (4 identifying strictures and 3 for intra-abdominal abscesses and peritonitis).[50]

Providers should consider the role of microbes in the pathogenesis and as a complication of NEC when microbes invade the intestinal epithelium and enter the bloodstream. Because NEC can clinically resemble sepsis, providers should obtain blood, stool, urine, and cerebrospinal fluid cultures and administer intravenous antibiotics.

Recommendations for initial antimicrobial therapy vary among experts. Some experts advocate the routine use of ampicillin and gentamicin. When perforation is diagnosed or necrosis is suspected, providers should add an agent with activity against anaerobes (e.g., clindamycin or metronidazole). Providers should add vancomycin if resistant *Staphylococcus* species are documented.[19,51] Some experts recommend immediate empiric use of vancomycin in addition to broad-spectrum gram-negative bacillus coverage.[52] However, the empiric use of vancomycin for possible coagulase-negative staphylococci must be balanced against the risk of selecting vancomycin-resistant enterococci. Reinforcement of strict handwashing is essential. Infection control measures such as barrier isolation and cohorting of affected infants and personnel may abort epidemics.

Routine inclusion of antimicrobial agents active against anaerobic bacteria does not seem to be indicated in NEC without perforation, but few well-controlled studies have been conducted. Clindamycin use was associated with increased strictures following stage II NEC in a small randomized study, as well as in a multicenter observational study using propensity matching of 1390 infants exposed to anaerobic therapy. However, mortality rates were decreased in infants with surgical NEC who received anaerobic therapy compared with infants who did not receive this therapy.[53,54]

Despite conservative management, including withholding of feedings, abdominal decompression, and antimicrobial therapy, some infants require more invasive therapy with surgical management. Indications for surgical intervention include pneumoperitoneum on abdominal radiography or cellulitis of the anterior abdominal wall. Both pneumoperitoneum and cellulitis are signs of perforation or gangrenous bowel. Abdominal radiography is repeated every 6 hours to assess the progression of NEC. Third-spacing of fluid may indicate intestinal inflammation and edema. Progressive neutropenia, thrombocytopenia, and metabolic acidosis are potential signs of progression and may indicate the need for exploratory operation.

The classic operative strategies have been relatively conservative, including resection of grossly gangrenous bowel and creation of a proximal enterostomy or, conversely, placement of a drain. In a prospective, randomized, multicenter study comparing laparotomy with drain placement in 117 preterm infants with birth weights <1500 g, no difference was reported between the 2 groups in mortality rates at 28 days after procedure, mortality rates at 90 days after procedure, or prolonged duration of total parenteral nutrition.[55] In another multicenter observational trial that followed 156 infants with surgical NEC or isolated intestinal perforation, mortality rates were not different for laparotomy compared with drain placement, but neurodevelopmental outcome at 18 to 22 months of adjusted age was better among infants with laparotomy.[56] Randomized clinical trials are ongoing to determine the effect of laparotomy compared with drain placement on longterm patient outcomes.

Prognosis and Complications

NEC is associated with significant mortality. In a multicenter cohort study of 1722 extremely low–birth weight infants, the incidence of death among those with NEC was twice that of infants who did not develop NEC ($P < 0.01$). The death rate did not change substantially over the 12-year period (1998–2009).

Epidemiologic studies indicate that the requirement for surgical treatment or bloodstream infection associated with NEC increases the risk for death. Of 208 infants who developed NEC, 53 of 87 (61%) with medical NEC and 50 of 121 (41%) with surgical NEC survived until hospital discharge.[57] The incidence of death among all infants with surgical NEC is approximately 50%.[39,58,59] Among 410 infants with NEC, an NEC-associated bloodstream infection nearly quadrupled the odds of requiring surgical intervention (odds ratio: 3.5; 95% confidence interval [CI] 1.98, 6.24), and tripled the odds of death (odds ratio: 2.9; 95% CI, 1.39, 5.97) when compared with infants who did not have bloodstream infection.[60]

Substantial morbidity also accompanies NEC. Preterm infants with NEC, particularly surgical NEC, have much higher risk for developmental delay than infants who do not have NEC.[61,62] Other acute and chronic complications of NEC often result in prolonged hospitalizations for affected infants (Box 58.3).[58,63]

Box 58.3

Complications of Necrotizing Enterocolitis

Intestinal or colonic strictures

Enterocolonic fistulas

Fluid and electrolyte imbalance

Malabsorption

Cholestasis

Anastomotic leaks and stenosis after surgical treatment

Short gut syndrome after surgical treatment

Morbidity related to the longterm effects of NEC on the gastrointestinal tract is seen in 10% to 30% of affected infants and is highest among infants with NEC who require surgical treatment. One of the most serious complications of NEC is short bowel syndrome. This condition occurs when more than 70% of the intestine is removed and is particularly difficult to manage if the terminal ileum and ileocecal valve cannot be preserved because of the tendency to injury of this area in NEC. The potential consequences of short bowel syndrome include malabsorption, extensive parenteral nutrition requiring prolonged venous access, bacterial overgrowth, and bowel transplantation.[64]

Advances in Understanding of Pathophysiology

The understanding of NEC pathophysiology continues to advance. Awareness of the following is increasing: (1) factors that influence the integrity of the neonatal epithelial barrier[65,66]; (2) the intricacies of innate immunity, particularly the influence of TLR4 on innate immunity[67]; and (3) the contribution of the gut microbiota of premature infants to the development of NEC.[32,68] The transformation of this information into clinically useful data for new therapies, early identification of infants with NEC, and prevention, is ongoing.

Prevention

Multiple strategies to prevent NEC have been proposed. Most common among these is the use of human milk as the primary nutrition source. In a meta-analysis of 9 randomized (or quasirandomized) controlled trials in 1070 infants who received infant formula or donor breast milk, feeding with formula significantly increased the risk of NEC (risk ratio: 2.77; 95% CI, 1.40–5.46).[69] An analysis of 1272 infants suggested that the benefits of human milk administration in the prevention of NEC are dose related. The incidence of NEC or death decreased for every 10% increase in the proportion of total intake that was human milk.[70] In a single multicenter, randomized clinical trial, a human milk–derived human milk fortifier was compared with a bovine milk–derived fortifier, the incidence of NEC was significantly reduced among those infants receiving an exclusively human milk–derived diet.[71]

Human milk may influence physiologic pathways that lead to NEC in several ways. Human milk may cause intestinal maturation and healing against insults through the presence of immune and growth factors, including platelet activating factor acetyl hydrolase, immunoglobulin A, cytokines, and epidermal growth factor, among others.[72] Human milk may also promote the growth of commensal bacteria.

Investigators also have evaluated the relationships among timing of feeding initiation, rate of feeding advancement, and the incidence of NEC. A meta-analysis of 9 randomized controlled trials of 1106 infants found no statistically significant difference in risk of NEC for infants who had feedings introduced at ≤4 days of life compared with infants who received first feedings >4 to 7 days after birth.[73] In a meta-analysis of 6 randomized controlled trials, including 618 infants, no difference was noted in the incidence of NEC between groups fed 15 to 20 mL/kg and those fed 30 to 35 mL/kg. However, infants fed at the slower rates took longer to regain birth weight and reach full enteral feedings.[74] Long periods of not feeding can cause gut atrophy and worsened inflammatory responses, which predispose infants to NEC.[13]

Administration of prophylactic probiotics or prebiotics is thought to prevent bacterial migration, replenish nonpathogenic bacteria, and enhance the host immune response, thereby preventing NEC. In a meta-analysis, administration of *Lactobacillus,* alone or in combination with *Bifidobacterium,* was associated with reduction of severe NEC (stage II or worse; risk ratio: 0.43; 95% CI, 0.33–0.56). The authors of this meta-analysis suggested that the evidence for probiotic use is robust enough to support practice change; however, the available data include little information about the safety, feasibility of product consistency, most effective dosing, and ideal timing of probiotic administration.[75] In a multicenter, randomized controlled trial of 400 infants, those infants who received probiotics alone (2%) or in combination with prebiotics (4%), had a lower incidence of NEC compared with infants receiving prebiotics or placebo alone (12%) ($P < 0.001$).[76]

As the understanding of NEC continues to advance, it is hoped that new therapies to decrease the incidence of NEC among low–

birth weight infants will be developed. Studies to investigate the benefits of increasing intestinal nitric oxide synthesis, modulating the immune system, improving surgical techniques, and altering the intestinal biota will be informative.

Enteric Diseases Transmitted Through Food, Water, and Zoonotic Exposures

Karen P. Neil, Jonathan S. Yoder, Aron J. Hall, Anna Bowen

More than 200 known pathogens and noninfectious agents can be transmitted through ingestion of food or water contaminated with viruses, bacteria, parasites, microbial or chemical toxins, metals, and prions or through contact with animals or their environments.[1] Enteric disease is one of the most common illness types resulting from foodborne, waterborne, or zoonotic transmission. Symptoms of enteric illness range from mild gastroenteritis to life-threatening sepsis and neurologic, hepatic, ocular, and renal syndromes. Children <5 years of age, pregnant women, older adults, and immunocompromised persons are at higher risk for serious illness. Despite improvements in water, sanitation, and hygiene, foodborne, waterborne, and zoonotic enteric diseases remain major public health problems in developed and developing countries.

Epidemiology

Foodborne Disease

The Centers for Disease Control and Prevention (CDC) estimates that 48 million domestically acquired foodborne illnesses occur in the United States each year, resulting in approximately 128,000 hospitalizations and 3000 deaths.[2,3] Among known pathogens, norovirus is the leading cause of foodborne illness in the US, followed by nontyphoidal *Salmonella*, *Clostridium perfringens*, and *Campylobacter*.[3] The highest incidence rates for nontyphoidal *Salmonella*, *Campylobacter*, *Shigella*, *Escherichia coli* O157, and *Yersinia enterocolitica* occur in children <5 years of age, and the highest rate of invasive *Cronobacter* spp. (formerly *Enterobacter sakazakii*) infections is among infants.[4,5] These 6 bacterial pathogens are estimated to cause >290,000 illnesses annually among children <5 years of age and to result in nearly 8000 hospitalizations and 64 deaths.[4,5] Nontyphoidal *Salmonella* is estimated to cause the most hospitalizations and deaths each year in this age group. Although norovirus causes approximately 50% of recognized foodborne illnesses associated with outbreaks in the US, the highest rates of hospitalizations and deaths associated with norovirus occur in adults ≥65 years old and older.[6] With widespread administration of antimicrobial agents to humans and feed animals, antimicrobial resistance has become increasingly prevalent among strains of *Salmonella*, *Campylobacter*, and *Shigella*.[7]

Most foodborne illnesses are not linked to outbreaks. However, data from foodborne illness outbreaks provide useful insights into important pathogens, new and high-risk food vehicles, and settings associated with illness. From 1998 to 2012, more than 16,500 foodborne disease outbreaks affecting more than 330,000 people in the US were reported to the CDC, with an annual average of >1000 outbreaks and >22,000 ill persons.[8–11] Norovirus continues to be the leading cause of confirmed, single-agent foodborne disease outbreaks in the US, followed by *Salmonella* species.[8]

Many different foods have been linked to foodborne illness outbreaks; poultry, fish, beef, unpasteurized dairy products, fruits, and vegetable row crops have been commonly implicated in recent foodborne outbreaks.[8–10] Contaminated produce (particularly leafy green vegetables) increasingly has been linked to foodborne outbreaks caused by norovirus, *Salmonella*, *E. coli* O157:H7 and other Shiga toxin producing–*E. coli* (STEC), *Listeria monocytogenes*, *Shigella* spp., *Cryptosporidium*, and *Cyclospora cayetanensis*.[11–29] Imported fresh raspberries, basil, cilantro, and snow peas have been linked to outbreaks of *Cyclospora* infection.[13,21,30] Despite its risk, unpasteurized (raw) milk continues to be sold legally in many states and sometimes is given to school groups who visit farms; more than 130 outbreaks linked to unpasteurized milk or cheese have been reported in the US since 1993,[8–10,31] and etiologic agents include norovirus, *Salmonella*, *Campylobacter*, *Staphylococcus aureus*, *Listeria monocytogenes*, and STEC.[31–34] During 2007 to 2012, most outbreaks associated with unpasteurized milk were caused by *Campylobacter* spp.[35] Formula-fed infants have a heightened risk of salmonellosis compared with breastfed infants, perhaps because they are not receiving immunologic protection from human milk or because of contamination of formula in the bottle.[36] Powdered infant formula is also associated with *Cronobacter* spp. (formerly *Enterobacter sakazakii*) infection in infants, which can result in sepsis and meningitis.[37] Commercial processed foods and ready-to-eat foods have also been implicated in outbreaks of *Salmonella*, *E. coli* O157, and *L. monocytogenes*, including prepackaged cookie dough, salami made with contaminated pepper, snack foods, and frozen microwaveable meals.[38–42] Ready-to-eat foods, such as salads and sandwiches, as well as self-service food items, often are implicated in norovirus and shigellosis outbreaks.[43,44] Additional information about vehicles associated with enteric disease etiologic agents is shown in Table 59.1.

TABLE 59.1

Characteristics and Diagnosis of Enteric Illnesses Caused by Microbes or Toxins

Etiology	Incubation Period	Signs and Symptoms	Duration of Illness	Selected Vehicles	Labo
BACTERIAL					
Bacillus anthracis	2 days to weeks	Nausea, vomiting, malaise, bloody diarrhea, abdominal pain	Weeks	Insufficiently cooked contaminated meat	Blood
Bacillus cereus (diarrheal toxin)	10–16 hr	Abdominal cramps, nausea, watery diarrhea	24–48 hr	Meats, stews, gravies, milk products, vegetable dishes	Durir consi quant testin stool

Bacillus cereus (preformed enterotoxin)	1–6 hr	Sudden onset of severe nausea and vomiting; possibly with diarrhea	24 hr	Improperly refrigerated cooked rice, meats	Durir consi quant testin emesi
Brucella abortus, Brucella melitensis, Brucella suis	7–21 days	Fever, chills, sweating, weakness, headache, myalgias, arthralgias, bloody diarrhea	Weeks	Raw milk, unpasteurized goat cheese, meats	Blood serol
Campylobacter jejuni	2–5 days	Fever, cramps, vomiting, diarrhea (can be bloody)	2–10 days	Raw and undercooked poultry, unpasteurized milk, contaminated water, animal contact	Stool media incub
Clostridium botulinum (preformed toxin)	12–72 hr	Vomiting, diarrhea, diplopia, dysphagia, descending muscle weakness, respiratory paralysis	Variable (days to months)	Home-canned foods with low acid content, improperly canned commercial foods, fermented fish, herb-infused oils, potatoes baked in foil, bottled garlic, foods held warm for extended periods	Stool, food for to food
Clostridium botulinum (infant)	3–30 days	Lethargy, weakness, hypotonia, poor head control, poor feeding, poor gag reflex, constipation	Variable	Honey, corn syrup	Stool, food for to food
Clostridium perfringens (toxin)	8–16 hr	Nausea, cramps, watery diarrhea; fever rare	24–48 hr	Meats, poultry, fish, gravy, dried or precooked foods, time- or temperature-abused foods	Stool be tes enter quant cultu organ CFU/ $>10^5$ C
Cronobacter spp.	Unknown	Diarrhea possible, sometimes bloody;	Variable; meningitis	Powdered infant formula	Blood cereb

		sepsis; meningitis	associated with brain abscesses and prolonged illness		cultu infan be tes and s healt
Enterotoxigenic *Escherichia coli* (ETEC)	24–72 hr	Cramps, possible vomiting, watery diarrhea	3 to >7 d	Contaminated water or food (often during international travel)	Stool (requ testin
Shiga toxin–producing *Escherichia coli* (STEC)	1–8 days	Abdominal pain, vomiting, diarrhea that becomes bloody; usually no fever	5–10 days	Undercooked beef (especially ground beef), unpasteurized dairy and juice, leafy green vegetables, sprouts, contaminated water, petting zoos or farms featuring ruminant animals	Stool O157 speci toxin done comm
Listeria monocytogenes	9–48 hr for gastrointestinal symptoms; 2—6 wk for invasive disease	Fever, myalgias, nausea, diarrhea; pregnant women may have a flu-like illness, and infection can cause premature delivery or fetal loss; infants born to infected mothers and immunocompromised patients can have bacteremia or meningitis	Variable	Soft cheeses, raw fruits and vegetables, hot dogs, delicatessen meats (especially turkey) and delicatessen salads	Blood cultu asym carria stool helpf
Salmonella spp.	24–72 hr	Fever, cramps, vomiting, diarrhea; S. *enteritidis* serotype Typhi and *S. enteritidis* serotype Paratyphi cause typhoid, characterized by fever, headache, constipation, myalgias, and abdominal pain	4–7 days	Poultry, eggs, beef, pork, unpasteurized milk or juice, raw fruits and vegetables (especially sprouts, melons, tomatoes), nuts; reptiles, amphibians, rodents, live poultry; typhoid is associated with international travel	Stool

Shigella spp.	12–72 hr	Fever, cramps, tenesmus, diarrhea that can be bloody and mucoid	4–7 days	Low infectious dose leading to person-to-person spread, particularly in childcare settings and within households, foods contaminated by ill food handlers, contaminated swimming venues (especially freshwater)	Stool
Staphylococcus aureus (preformed enterotoxin)	1–6 hr	Sudden onset of severe nausea and vomiting; possibly with diarrhea and fever	24–48 hr	Improperly refrigerated meats, potato and egg salads, cream pastries	Stool, food for to cultu indica
Vibrio cholerae (toxin)	24–72 hr	Profuse watery diarrhea, vomiting; severe dehydration and death possible within hours	3–7 days	Contaminated water or food during international travel	Stool (requ testin
Vibrio parahaemolyticus	2–48 hr	Cramps, nausea, vomiting, watery diarrhea	2–5 days	Undercooked or raw seafood	Stool (requ testin
Vibrio vulnificus	1–7 days	Vomiting, abdominal pain, diarrhea, bacteremia, wound infections; more common in immunocompromised persons and in those with chronic liver disease	2–8 days	Undercooked or raw shellfish, especially oysters; wounds exposed to seawater	Stool, blood (requ testin
Yersinia enterocolitica and *Yersinia pseudotuberculosis*	24–48 hr	Appendicitis-like symptoms (fever, abdominal pain, diarrhea, vomiting), typically in older children and young adults. *Y. pseudotuberculosis* may cause scarlatiniform rash	1–3 wk	Undercooked pork, unpasteurized milk, tofu, water; infant infections have been associated with caregivers who handled	Stool, blood (requ testin serolo possil and r labora

				chitterlings	
VIRAL					
Hepatitis A	28 days (15–50 days possible)	Diarrhea, jaundice, flu-like symptoms	Variable; 2 wk–3 mo	Shellfish, raw produce, frozen berries, drinking water, foods contaminated by infected food worker	Increa biliru testin
Norovirus	12–48 hr	Nausea, vomiting, watery, large-volume diarrhea; fever rare	1–3 days	Shellfish, salads, sandwiches, ready-to-eat foods handled by infected food worker, person-to-person spread	Rever transc stool; analy genot
Rotavirus	1–3 days	Low-grade fever, vomiting, watery diarrhea; temporary lactose intolerance possible	4–8 days	Foods contaminated by ill food handlers	Stool
Other viral agents (astroviruses, caliciviruses, adenoviruses, parvoviruses)	12–72 hr	Headache, fever possible, nausea, vomiting, diarrhea, malaise	2–9 days	Foods contaminated by ill food handlers; shellfish	Antig PCR, testin
PARASITIC					
Angiostrongylus cantonensis	1 wk to >1 mo	Severe headache, neck stiffness, nausea, vomiting, paresthesias, seizures, other neurologic symptoms	Weeks to months	Raw or undercooked snails or slugs, infected crabs or freshwater shrimp, contaminated raw produce	CSF p prote and e serolo
Cryptosporidium	7 days (2–28 days possible)	Low-grade fever, cramps, nausea, diarrhea (usually watery)	May remit and relapse over weeks to months	Recreational or drinking water; food or water contaminated by ill food handler; raw milk; camping or backpacking; petting zoos; person-to-person spread	Antig
Cyclospora cayetanensis	7 days (1–14 days possible)	Cramps, nausea, vomiting, anorexia, weight loss, diarrhea (usually watery), fatigue	May remit and relapse over weeks to months	Imported fresh produce (berries, lettuce); international travel	Requ testin stool
Entamoeba	2 days–4 wk	Lower abdominal	May last	Food or water	Serial

histolytica		pain, bloody diarrhea	weeks to months	contaminated by ill person; international travel	exam cysts serol
Giardia	1–4 wk	Cramps, diarrhea, flatulence	Days to weeks	Food or water contaminated by ill person; recreational fresh water; camping/back-packing; international travel; person-to-person spread	Serial exam
Toxoplasma gondii (enteric exposure)	6–10 days	Generally asymptomatic; 20% may develop cervical lymphadenopathy or flu-like symptoms; Immunocompromised patients can have CNS disease, myocarditis, or pneumonitis	Months	Soil contaminated with cat feces, raw or partially cooked meat	Isolat obser paras or oth PCR
Toxoplasma gondii (prenatal exposure)		Few symptoms at birth; later, mental retardation, cerebral palsy, impaired vision, seizures	Months to years	Vertically transmitted, when mother is acutely infected during pregnancy	Isolat umbi placen blood blood fluid, serol
Trichinella spiralis	1 day–8 wk	Acute: fever, nausea, vomiting, abdominal pain, diarrhea, muscle soreness, weakness; later, occasionally cardiac and neurologic complications	Months	Raw or undercooked meat (usually pork or wild game)	Serol larva biops
NONINFECTIOUS					
Aflatoxin	Variable and dose dependent	Vomiting, jaundice, hemorrhagic liver necrosis, liver cancer, death	Variable and dose dependent; usually days to weeks	Fungal contamination of improperly dried and stored grains, nuts, spices, particularly in Africa and Asia	Ident aflato or afl deriv or bl
Algal toxins	Variable and dose dependent	Skin irritation, stomach cramps, vomiting, nausea, diarrhea, fever, sore throat, headache, muscle and joint pain, blisters of the mouth, liver damage	Variable and dose dependent	Exposure by physical contact, inhalation, or ingestion to water, or dietary supplements	Labor detec cyano other toxin- algae cyano toxins

				contaminated by harmful algae or toxins (e.g., cyanobacteria, red tide)	speci body, drink suppl dieta
Antimony	Variable and dose dependent; usually minutes to hours	Vomiting, metallic taste	Variable and dose dependent	Metal food containers; intentional or unintentional contamination of foods	Ident metal food,
Arsenic	Variable and dose dependent; usually minutes to hours	Vomiting, cramps, diarrhea, encephalopathy and peripheral neuropathy with high-dose exposure; lower-dose, longterm exposure may not produce GI symptoms	Variable and dose dependent; usually several days	Contaminated food or water	Urine
Cadmium	Variable and dose dependent; usually minutes to hours	Abdominal pain, salivation, nausea, vomiting, myalgia	Variable and dose dependent	Seafood, oysters, clams, lobster, grains, peanuts; intentional or unintentional contamination of foods	Blood levels of me
Ciguatera toxin	2–6 hr	GI: abdominal pain, nausea, vomiting, diarrhea	Variable and dose dependent; usually days to weeks	Reef fish (e.g., grouper, red snapper, amberjack, barracuda)	Radi in fis
	3 hr	Neurologic: paresthesias, reversal of hot or cold, pain, weakness	Variable and dose dependent		
	2–5 days	Cardiovascular: bradycardia, hypotension, T-wave abnormalities	Variable and dose dependent		
Copper	Variable and dose dependent; usually minutes to hours	Nausea, vomiting with blue or green vomitus	Variable and dose dependent	Copper food or beverage container; intentional or unintentional contamination of foods	Ident metal food
Lead	Chronic or acute	Irritability, anorexia, abdominal pain, cerebral edema, encephalopathy, seizures, death	Weeks to months	Drinking water; foods from lead-containing cans or grown in lead-contaminated soil; lead-	Veno levels

				containing kitchen ware (nonfood or nonbeverage sources, e.g., batteries, jewelry, and paint more common)	
Mushroom toxins, short-acting (museinol, muscarine, psilocybin, coprius artemetaris, ibotenic acid)	<2 hr	Dependent on mushroom species: confusion, diaphoresis, visual disturbance, salivation, vomiting, diarrhea, disulfiram-like reaction	Hours to few days	Wild mushrooms (cooking may not destroy toxins)	Mush identi toxin speci
Mushroom toxins, long-acting (amanitin)	6–24 hr (diarrhea); 2–4 days (liver failure)	Cramps, diarrhea, hepatic and renal failure, coagulopathy, seizures, death	2–8 days	Wild mushrooms	Mush identi toxin speci
Nitrite	1–2 hr	Headache, dizziness, loss of consciousness, nausea, vomiting, cyanosis (blue baby syndrome)	Hours to days	Well water; cured meats; spinach, beets, and other vegetables exposed to excessive nitrification	Ident eleva levels or uri meth
Pesticides (organophosphates or carbamates)	Variable and dose dependent; usually minutes to a few hours	Headache, nervousness, twitching, convulsions, miosis, cramps, nausea, vomiting, diarrhea	Weakness or neuropathy may last weeks	Pesticide-contaminated foods	Analy blood
Puffer fish (tetrodotoxin)	<30 min	Paresthesias, ascending paralysis, respiratory failure, abdominal pain, vomiting, diarrhea, death	Death in 4–6 hr	Puffer fish	Detec tetroc
Scrombroid (histamine)	1 min–3 hr	Dizziness, paresthesias (burning sensation of mouth, throat and skin), flushing, urticaria	3–6 hr	Fish: bluefin, tuna, skipjack, mackerel, marlin, escolar, mahi mahi	Detec hista
Shellfish toxins (diarrheic, neurotoxic, amnesic, paralytic)	30 min–2 hr (diarrheic)	Fever, headache, nausea, vomiting, abdominal pain, diarrhea	Hours to 2–3 days	Shellfish from Gulf of Mexico and Florida coast: mussels, oysters, scallops	Detec toxin
	Minutes to a few hours (neurotoxic)	Dizziness; reversal of sensations of hot and cold; tingling or numbness of lips,	Variable and dose dependent		

		tongue and throat; vomiting; diarrhea; myalgias			
	24–48 hr (amnesic)	Confusion, memory loss, disorientation, seizures, coma, abdominal pain, vomiting, diarrhea	Variable and dose dependent		
	30 min–3 hr (paralytic)	Diarrhea, nausea, vomiting, paresthesias of mouth and lips, weakness, dysphagia, dysphonia, respiratory paralysis	Variable and dose dependent; usually days		
Sodium fluoride	Minutes to 2 hr	Salty or soapy taste, numbness in mouth, vomiting, diarrhea, dilated pupils, spasms, pallor, shock; severe hypocalcemia, hyperkalemia	Variable and dose dependent	Dry foods (e.g., powdered milk, flour, baking powder, cake mixes) contaminated with sodium fluoride–containing pesticides	Detec vomit wash
Thallium	Variable and dose dependent; usually minutes to hours	Acute: nausea, vomiting, diarrhea; delayed: painful paresthesias, motor polyneuropathy, hair loss	Variable and dose dependent; usually days	Contaminated food	Detec blood
Tin	Variable and dose dependent; usually minutes to hours	Nausea, vomiting, diarrhea	Variable and dose dependent	Metallic container; intentional or unintentional contamination of foods	Serun levels toxin
Vomitoxin	Minutes to a few hours	Nausea, headache, abdominal pain, vomiting	Variable and dose dependent	Grains (e.g., wheat, corn, barley)	Detec food
Zinc	Variable and dose dependent; usually minutes to hours	Stomach cramps, nausea, vomiting, diarrhea, myalgias	Variable and dose dependent; usually hours to days	Metallic container; intentional or unintentional contamination of foods	Detec food, saliva

ALT, alanine aminotransferase; CDC, Centers for Disease Control and Prevention; CFU, colony-forming unit; CNS, central nervous system; CSF, cerebrospinal fluid; GI, gastrointestinal; IV, intravenous; PCR, polymerase chain reaction; TMP-SMX, trimethoprim-sulfamethoxazole.

Adapted from Centers for Disease Control and Prevention. Diagnosis and management of foodborne illnesses: a primer for physicians and other health care professionals. MMWR Morb Mortal Wkly Rep 2004;53(RR-04):1–33.

Toxin-mediated enteric illnesses caused by *C. perfringens*, *Bacillus cereus*, and *S. aureus* are estimated to cause 1.3 million illnesses annually in the US.[45] Illness outbreaks are most commonly linked to errors in food handling, such as holding foods at room or outdoor temperatures for several hours, improper reheating practices, and slow cooling of foods.[45] *C. perfringens* spores are ubiquitous in the environment; illness occurs after ingestion of contaminated food with resulting sporulation and toxin production in the gastrointestinal tract.[46] Meat and poultry are most commonly implicated in outbreaks.[45,47] *B. cereus* has been isolated from a wide variety of foods, including rice, spices, dried foods, vegetables, and dairy products.[48] Outbreaks of the short-incubation "emetic syndrome" of *B. cereus* food poisoning most commonly are associated with rice, particularly fried rice.[45] Outbreaks of longer-incubation "diarrheal syndrome" have been linked to a variety of foods, including vegetables, milk products, sauces, and pudding, in addition to meat products.[45,48] Staphylococcal food poisoning has been linked many different foods, including cooked meats and poultry, custard or cream-filled baked goods, dairy products, sandwiches, and salads.[45,49]

Foodborne botulism is caused by ingestion of foods contaminated with preformed botulinum toxin. In the US, foodborne botulism is typically associated with consumption of home-canned, low-acid foods, such as vegetables and fish.[50] However, commercially produced products such as carrot juice and canned chili have been linked to past outbreaks.[51,52] Infant botulism occurs after swallowed spores of *Clostridium botulinum* (and rarely, other neurotoxigenic *Clostridium* spp.) germinate, temporarily colonize the large intestine, and produce botulinum toxin.[53] Honey has been implicated as the source of *C. botulinum* spores in some cases of infant botulism.[54]

Histamine fish poisoning is commonly associated with scombroid fish (e.g., tuna, mackerel, skipjack), although other fish have been implicated in illness.[55] Ciguatera fish poisoning has been associated with more than 400 species of fish, including barracuda, snapper, amberjack, and grouper.[56] Shellfish, especially bivalve mollusks, are important vehicles of foodborne illness, particularly because they are often consumed raw. Shellfish can be colonized naturally with pathogenic *Vibrio* organisms, including *Vibrio* *vulnificus*, *Vibrio cholerae* non-O1, *Vibrio parahaemolyticus*, and *Vibrio mimicus*. As filter feeders, shellfish concentrate pathogens from contaminated water, including hepatitis A virus, norovirus, toxigenic *V. cholerae* O1, *Shigella*, and *Plesiomonas*.[57]

Foodborne outbreaks of heavy-metal poisoning are most often associated with acidic beverages such as lemonade, fruit punch, and carbonated drinks that have been stored in corroded metallic containers.[58] Mushroom poisoning occurs most often in the spring, late summer, and fall and is associated with species-specific syndromes (see Table 59.1).[59,60]

Waterborne Disease

Enteric waterborne disease resembles disease resulting from contamination of food and can be caused by many of the same pathogens. Large waterborne disease outbreaks resulting in enteric illness have been caused by *Cryptosporidium*, *Campylobacter*, *E. coli*, *Salmonella*, *Shigella*, chemical agents, hepatitis A virus, norovirus, *Giardia*, and other agents.[61–73] *Cryptosporidium*, a chlorine-tolerant protozoa, has been associated with 16 drinking-water outbreaks from between 1971 and 2013; a single outbreak in Milwaukee accounted for an estimated 403,000 cases.[61]

An estimated 16.4 million cases of acute gastroenteritis are associated with public drinking water systems annually.[74] However, drinking water–associated outbreaks in the US have been decreasing, particularly outbreaks associated with public water systems.[75] This change corresponds with the implementation of federal regulations designed to reduce illnesses associated with public water systems. Privately owned systems tend to serve fewer people and do not fall under the drinking water regulations established by the US Environmental Protection Agency (EPA) to protect water quality in public drinking water systems. Increased illnesses among children have been associated with the use of water from private wells.[76] Water system contamination resulting in drinking water–associated outbreaks can occur at a variety of points, including the water source, treatment processing, storage, distribution system, premise plumbing, and point of use. In studies of public systems using ground water, human enteric viruses, such as enteroviruses and norovirus, have been isolated from aquifers that may have been contaminated from surface water intrusion or sewage discharges.[77,78] The broader public health impact of such contaminated ground water could be substantial because approximately 45% of the US population is supplied by ground water, either through public or individual water systems.[79]

In contrast, the number of enteric disease outbreaks associated with recreational water has dramatically increased.[73] Recreational water illnesses are caused by pathogens transmitted by ingesting, inhaling aerosols or by having contact with contaminated water in pools, hot tubs, interactive fountains, lakes, rivers, oceans, and so forth. Recreational water illnesses also can be caused by chemicals in the water or by chemicals that volatilize from the water and cause indoor air quality problems. *Cryptosporidium* has become the leading cause of enteric illness outbreaks associated with treated recreational water (e.g., pools and interactive fountains). *Cryptosporidium* accounted for >75% of the outbreaks associated with treated recreational water reported to CDC during 2001 to 2010.[73]

Water used for recreational purposes may be treated or untreated. *Cryptosporidium* is most commonly implicated in outbreaks associated with treated recreational water. Because *Cryptosporidium* is extremely tolerant to chlorine levels used in treated water, these outbreaks can occur even in well-maintained facilities and have the potential to expand community wide, starting in recreational water transmission and moving by person-to-person transmission into childcare programs and other settings.[80–82] Outbreaks of gastrointestinal illness associated with untreated water primarily are caused by bacteria and viruses (e.g., *E. coli*, norovirus, *Shigella*) and usually are linked to swimming in lakes or ponds.[73] This finding suggests that swimmers themselves can be important sources of water contamination.

Zoonotic Disease

Zoonotic transmission of enteric pathogens can occur through direct or indirect exposure to pets, livestock, and other animals. A 2012 study estimated that 14% of all illnesses caused by *Campylobacter* spp., *Cryptosporidium*, *E. coli* O157:H7 and other STEC, *L. monoctyogenes*, nontyphoidal *Salmonella*, and *Yersinia* *enterocolitica* are attributable to animal contact.[83] This estimate translates to a total of almost 450,000 illnesses each year for these pathogens combined. Children <5 years of age are at higher risk for serious infections, as are pregnant women, people >65 years of age, and people with immunodeficiencies.[84]

Animal exposure can occur in many venues, including homes, farms, zoos, fairs, petting zoos, camps, childcare centers, and schools. The primary mode of transmission is the fecal-oral route. Because animal fur, hair, skin, and saliva can become contaminated with fecal organisms, transmission can occur when persons pet, touch, or are licked by animals.[85] Enteric pathogens also can contaminate the environment (e.g., water sources, soil, bedding) and persist in animal housing areas for long periods. The following have been cited as reasons for zoonotic infection: direct contact with animals, particularly young animals; indirect exposure through contamination of food, water, or the environment; and inadequate hand hygiene.[85,86]

Contact with animals in public settings provides opportunities for pathogen transmission to visitors. From 1996 to 2012, approximately 200 human infectious disease outbreaks linked to interacting with animals in public settings were reported to the CDC.[85] Multiple *E. coli* O157 outbreaks have been linked to petting zoos.[85,87–89] Turtles and other reptiles, amphibians, rodents, and live poultry are well-known sources for zoonotic transmission of human *Salmonella* infections. Multiple large, multistate salmonellosis outbreaks in recent years were linked to small turtles, chicks, ducklings, and other live poultry purchased from mail-order hatcheries for backyard poultry flocks.[90–95] Outbreaks also have been linked to contaminated dry dog and cat foods, pet treats, frozen rodents used to feed pet reptiles, and products used for educational activities in schools.[96–102] Cattle are the major source of zoonotic transmission of human cryptosporidiosis, although other mammals can be infected.[103–105] Zoonotic transmission of *Giardia* to humans and the relative importance of animal contamination of food and water are being reexamined because of advances in molecular epidemiology. *Giardia* infects nearly all classes of vertebrates, including domestic animals and wildlife; however, molecular characterization has identified relatively species-specific genetic *Giardia* assemblages.[106]

Pathogenesis and Clinical Syndromes

Enteric diseases are often classified according to the mechanism of pathogenesis: ingestion of various classes of chemicals or preformed toxins, in vivo production of bacterial toxins, direct pathogen attachment and local invasion, or disseminated infection. Considering the clinical syndrome is more useful for the diagnosis of enteric illness. The cause of an enteric illness is suggested by clinical symptoms, the incubation period, and epidemiologic clues. Laboratory testing is required to confirm the identity of specific pathogens. An outbreak should be suspected when ≥2 people who have shared a common exposure (e.g., food, water, or animal) develop the same acute illness, most often characterized by nausea, vomiting, diarrhea, systemic, or neurologic symptoms. For additional information, refer to Table 59.1 and pathogen-specific chapters.

Enteric Disease Surveillance and Outbreak Detection

Medical care providers play essential roles in public health surveillance and the timely detection of enteric disease outbreaks because they are frequently the first persons to be contacted by persons with foodborne, waterborne, or zoonotic illness. Prompt diagnosis and reporting of enteric infections to state and local public health jurisdictions as required by law can aid recognition and mitigation of illness outbreaks. Currently, many outbreaks of enteric illnesses go undetected because they are misinterpreted as illnesses caused by person-to-person spread. Stool examinations and cultures may not be performed because these tests are not considered cost-effective for an individual patient or may not lead to specific therapy, despite providing a public health benefit. Culture-independent diagnostic tests are becoming more widely available for the clinical diagnosis of bacterial enteric infections, and results are not always confirmed by isolating bacteria from culture.[107] However, detailed characterization of bacterial isolates obtained from patients' cultures is necessary to distinguish among strains of pathogens and detect foodborne outbreaks. In addition, timely reporting, public health investigation, and use of rapid subtyping methods can help identify outbreaks, detect emerging pathogens, identify new vehicles and modes of transmission, and prevent additional illness. If an enteric disease outbreak is suspected, appropriate clinical specimens, including cultures, should be collected for laboratory testing if possible, and clinicians should notify local public health officials.

As the food production system has become more centralized, contaminated food can be distributed widely throughout the US and cause illnesses across multiple jurisdictions.[7] This situation can result in a few illnesses within each local or state public health jurisdiction, thereby making it difficult for local public health officials to recognize that illnesses in their jurisdiction are part of a more widely disseminated outbreak. PulseNet USA is a national network of public health and food regulatory laboratories started in 1996 with the aim of enhancing bacterial enteric disease outbreak detection and investigation.[108] Clinical laboratories send bacterial isolates obtained from culture of persons ill with enteric pathogens to PulseNet laboratories for further characterization. PulseNet performs molecular subtyping of these isolates to distinguish among strains of bacterial enteric pathogens, including *Campylobacter jejuni*, STEC, *Shigella*, *L. monocytogenes*, and *Salmonella*. The resulting molecular fingerprints are shared electronically and are uploaded into national databases at the CDC. These databases are routinely monitored to identify clusters of isolates that are indistinguishable or very highly similar by molecular subtyping, which may indicate an outbreak. PulseNet refers identified clusters to the CDC and state epidemiologists for investigation. By quickly compiling and comparing molecular subtyping data from enteric bacteria isolated from ill persons nationwide, PulseNet has aided in the detection of widely dispersed foodborne disease outbreaks. The main subtyping method used by PulseNet is pulsed-field gel electrophoresis, but other advanced methods such as next-generation whole genome sequencing are beginning to be used for outbreak detection and response.

A limitation of this surveillance system is that the current methods used by PulseNet require a bacterial isolate obtained from culture for public health laboratories to be able to characterize the bacterial strain further by serotyping and molecular subtyping. Although culture-independent diagnostic tests have several advantages, their increased use could have a substantial impact on public health surveillance and the ability of PulseNet to detect outbreaks.

Because water, with the exception of bottled water, is normally not a widely distributed product, most detected waterborne disease outbreaks are confined geographically to the service area, and multistate outbreaks are rare.[62,75] Illnesses associated with recreational water that does not attract patrons from a large geographic area (e.g., a local community pool) tend to be confined to a single community; conversely, illnesses associated with recreational water that attracts patrons from more geographically dispersed area (e.g., waterparks and oceans) can involve residents of a wide area. Dispersion of affected people may decrease the likelihood that the outbreak will be detected.[73]

Recognition of an outbreak can lead to removal of contaminated food items from the marketplace or correction of contaminated drinking water systems or recreational water venues and enhance industry and regulatory control measures to prevent contamination in the future. A list of nationally notifiable infectious conditions in the US can be found at: http://wwwn.cdc.gov/nndss/conditions/. State health departments can provide additional information about reporting infectious diseases within their jurisdictions.

Diagnosis

Epidemiologic Clues

The incubation period, clinical syndrome, and exposure history (including foods consumed and how they were prepared, as well as water and animal exposures) provide clues to the pathogenic etiologic agents of enteric disease, but a definitive diagnosis requires laboratory confirmation. The incubation period often is underestimated or unknown. Patients and clinicians may focus incorrectly on the most recent meals and fail to consider water or animals as potential sources of disease transmission. Most bacterial, viral, and parasitic enteric infections are transmitted by the fecal-oral route through ingestion of contaminated food or water.

Persons, especially young children, can become infected through person-to-person transmission or transmission by fomites without eating the implicated food, ingesting the implicated water, or directly handling animals. Toxin-mediated illnesses from organisms such as *S. aureus*, *B. cereus*, and *C. perfringens* are often linked to foods held at improper temperatures after cooking. A history of eating home-canned foods or feeding an infant honey should raise the index of suspicion of foodborne botulism or infant botulism, respectively, in a clinically compatible illness. Recent exposure to animals or animal environments can indicate a zoonotic route of transmission. A careful exposure history should include animal contact (both in and outside the household), drinking water source, recreational water use, and food and beverages consumed during at least the previous 7 days.

Laboratory Diagnosis

Appropriate collection and processing of clinical specimens and environmental samples are essential for confirming the cause of foodborne, waterborne, and zoonotic diseases. Because of the large number of different specimens, techniques, and culture media needed to evaluate all potential causes, it is most efficient to plan the laboratory investigation based on clinical or epidemiologic suspicion. Where culture-independent diagnostic tests are used, stool specimens should be routinely collected and cultured if evidence indicates bacterial infection.[107] Stool specimens and sera can be obtained early in the investigation and stored for later studies. Table 59.1 summarizes the principal laboratory tests recommended for diagnosis.[109]

All *Salmonella* spp., *Shigella* spp., STEC, *Vibrio* spp., and *L. monocytogenes* isolates should be forwarded to the state public health laboratory for full characterization for surveillance and outbreak detection purposes.[107] Laboratory diagnosis of norovirus infection relies primarily on polymerase chain reaction–based assays in public health and research laboratories. Ideally, whole stool samples to be tested for norovirus should be collected within 10 days after illness onset and kept refrigerated but not frozen.[110] Molecular subtyping through sequence analysis is facilitated in the US through CaliciNet, a national network of public health and regulatory laboratories that contribute to a database of norovirus genetic sequences obtained during investigations of disease clusters.[111] For both *Cryptosporidium* and *Giardia,* molecular testing can be reliably performed on non–formalin-preserved stool specimens that are refrigerated or frozen. Molecular testing is used increasingly in reference diagnostic laboratories to determine species and genotypes of these parasites and thus enhance outbreak investigations.[112] *Cyclospora* testing must be specifically requested of the laboratory and is best diagnosed with examination of at least 3 stool specimens.

Water testing, both in the context of drinking water and of recreational water outbreaks, also is useful during outbreak investigations. Ultrafiltration methods have been developed by which large volumes of water can be filtered in a relatively short time, and the filtrate and filter can then be shipped to reference diagnostic laboratories for analysis.[113] Other water-related media, such as filter cartridges and filter backwash from swimming pools, also can be tested.

Additional information on the collection of specimens for diagnosis and the investigation of enteric disease outbreaks is available at https://www.cdc.gov/foodsafety/outbreaks/investigating-outbreaks/specimen-collection.html and https://www.cdc.gov/healthywater/emergency/preparedness-resources/outbreak-response.html.

Management

Supportive care is central to the management of acute foodborne, waterborne, or zoonotic infectious diarrheal illness. Careful replacement of fluid and electrolyte losses is crucial, particularly in infants. For patients with mild to moderate dehydration, even with some vomiting, oral replacement with appropriate electrolyte solutions is the preferred treatment.[114] Antiemetic agents may be useful for patients with severe or prolonged vomiting, if toxins are not suspected as the cause. Antiperistaltic agents are not recommended for young children or patients with signs of enteroinvasive disease, such as fever or bloody diarrhea.[114] Bismuth subsalicylate provides symptomatic relief and has in vitro activity against norovirus, *E. coli* O157:H7, *Salmonella*, and *Shigella*[115,116]; however, theoretical concerns remain about its use in children, including the potential for excess salicylate absorption and the possibility of precipitating Reye syndrome.[117–119] Certain strains of probiotics have been found useful in hastening the recovery of children from acute diarrheal episodes.[120,121]

For severe illnesses caused by certain confirmed infections, notably listeriosis, shigellosis, enterotoxigenic and enteroinvasive *E. coli* infections, typhoid fever, cholera, cyclosporiasis, giardiasis, and cryptosporidiosis, antimicrobial therapy is indicated. Antimicrobial agents usually are not indicated for salmonellosis, except in very young children, persons with immunodeficiency, or patients with invasive salmonellosis. Outbreaks of salmonellosis and shigellosis have been caused by bacterial strains resistant to multiple antimicrobial agents; antimicrobial therapy for these patients should thus be used only when needed and tailored to the specific susceptibility profile of the pathogen. The role of antimicrobial therapy is less clear for treatment of diarrheal illness caused by *Y. enterocolitica, Campylobacter, V. parahaemolyticus, Aeromonas,* and *Plesiomonas,* but therapy may have a role in severe or prolonged gastrointestinal tract illness caused by these pathogens. The association between antimicrobial agents and increased risk of hemolytic uremic syndrome is not clear.[122–128] Therefore, antimicrobial agents are not recommended for children with *E. coli* O157:H7 and other STEC infections. No specific antiviral agents are available for the treatment of norovirus infections. Additional information about antimicrobial therapy is available in the pathogen-specific chapters.

Medical care providers who suspect botulism should immediately contact their state health departments. Most pediatric botulism cases are infant botulism. The California Infant Botulism Treatment and Prevention Program provides consultation and human botulism immune globulin intravenous (BIG-IV or BabyBIG) for suspected cases of infant botulism (telephone: 510-231-7600). For cases of suspected botulism among older children, the state health department contacts the CDC to arrange for clinical consultation by telephone and, if indicated, release of botulinum antitoxin. The CDC's 24-hour telephone number for state health departments to report possible botulism cases, obtain emergency consultation, and request botulinum antitoxin is 770-488-7100.

Patients with ciguatera or paralytic shellfish poisoning must be observed closely for evidence of respiratory compromise. Preliminary data suggest that intravenously administered mannitol may ameliorate the acute neurologic symptoms of severe ciguatera, and tocainide may improve the dysesthesias, but definitive data are lacking.[129–131] Symptoms of histamine fish poisoning may respond to antihistamines and histamine H_2-receptor antagonists. In patients with bronchospasm, epinephrine may be required.

For most patients with mushroom poisoning and symptom onset <6 hours after exposure, supportive care is adequate.[59,132] Uneaten mushrooms should be saved, and mycologists or experts in poison control (American Association of Poison Control Centers' Poison Help Line: 800-222-1222) should be consulted for species identification and possible use of specific antidotes. Onset of symptoms ≥6 hours after ingestion suggests *Amanita* poisoning, which can be lethal; a poison control center should be consulted for management advice. Liver transplantation may be required in patients with severe *Amanita* poisoning. Pyridoxine hydrochloride may be useful in cases of *Gyromitra* ingestion manifesting with seizures refractory to benzodiazepine therapy.[133]

Therapy for acute heavy-metal poisoning is supportive, although chelation can be helpful in some circumstances.[134] Antiemetic agents are contraindicated. Very severe cases of toxicity may require use of specific antidotes, and a medical toxicologist or poison control center should be consulted. The American Association of Poison Control Centers' toll-free Poison Help Line (800-222-1222) is available 24 hours/day to assist with cases of suspected intoxication.

Complications

The most common complications of foodborne, waterborne, and zoonotic diarrheal illnesses are dehydration, electrolyte abnormalities, and hypoglycemia. Children and older people are more susceptible to these complications. Severe vomiting can result in subconjunctival hemorrhage, syncope, or Mallory-Weiss esophageal tears. Enteric infection with *Salmonella* spp., *Y. enterocolitica, Vibrio* species other than *V. cholerae, Campylobacter* spp., *Cronobacter* spp., and *Shigella* spp. other than *S. sonnei* can be complicated by bloodstream infection or focal extraintestinal infections, such as osteomyelitis, endocarditis, endarteritis, or meningitis. Infants also are at increased risk for bloodstream infection and disseminated infections caused by common bacterial pathogens, particularly *Salmonella* spp. People with defects of cellular immunity (e.g., human immunodeficiency virus infection, leukemia, lymphoma), reticuloendothelial function (e.g., sickle-cell disease, malaria), and iron overload syndromes also have increased risk of bloodstream infection with *Salmonella* and *Campylobacter*.[135–137] People with immunosuppressing conditions are also at risk for disseminated disease, malabsorption, or death caused by *Cryptosporidium*.[138] *Listeria* infection during pregnancy can result in miscarriage, stillbirth, or neonatal sepsis.[139] Postinfectious syndromes have been recognized as important consequences of enteric infections, including the following: hemolytic uremic syndrome after infections with *E. coli* O157:H7[140]; reactive arthritis after salmonellosis, shigellosis, campylobacteriosis, and giardiasis[141–143]; and Guillain-Barré syndrome after campylobacteriosis.[144] Norovirus infections have been associated with necrotizing enterocolitis in neonates, chronic diarrhea in immunosuppressed patients, and postinfectious irritable bowel syndrome.[145–147]

Prevention

Food and Water

Clinicians should counsel patients and their families about ways to minimize their risk of foodborne illness. General food safety measures include the following: thorough handwashing before preparing and eating food and after handling raw meat, poultry, or eggs; cleaning surfaces and equipment used for preparation of raw foods to avoid cross-contamination; separating raw meat, poultry, and eggs from cooked or ready-to-eat foods; cooking food to the recommended minimum safe internal temperature; storing foods at temperatures too low (<4°C) or too high (>60°C) to support bacterial growth; and avoiding preparing or serving food for others during and immediately after a gastrointestinal illness.[148] Exclusion of ill workers from food preparation settings, frequent handwashing with soap and water, and eliminating bare-hand contact with ready-to-eat foods are can help minimize the risk of contamination with human pathogens, such as norovirus and *Shigella*. Raw foods of animal origin require particular attention, including poultry, beef, pork, unpasteurized (raw) milk, uncooked eggs, and uncooked shellfish. Cross-contamination of cooked foods from raw foods through contaminated surfaces and food preparation equipment is a common but avoidable error. Widespread use of hepatitis A vaccine will reduce foodborne transmission of hepatitis A virus. Routine typhoid vaccination is not recommended in the US, but typhoid vaccination is recommended for travelers to areas where typhoid fever is a recognized risk.[149] Updated educational information and materials about preventing foodborne illness are available at several websites (www.cdc.gov/foodsafety/, www.foodsafety.gov, www.nal.usda.gov/food-safety, and https://www.nal.usda.gov/fsrio/food-safety-topics).

People at greatest risk of severe disease (i.e., young children and persons with chronic liver disease, decreased gastric acidity, and acquired or congenital immunodeficiency), as well as people who seek to minimize their risk of illness, should avoid foods such as raw or undercooked shellfish, raw sprouts, unpasteurized milk products, unpasteurized juices, and raw or incompletely cooked eggs, poultry, or meat. To reduce the risk of listeriosis, persons at higher risk for infection (including pregnant women, adults >65 years old, and people with weakened immune systems) should avoid consuming the following: unpasteurized milk; hot dogs, luncheon meats, cold cuts, other delicatessen meats, or fermented or dry sausages unless they are heated to an internal temperature of 165°F or until steaming hot just before serving; soft cheese unless it is labeled as made with pasteurized milk; refrigerated smoked seafood; and, refrigerated pâtés or meat spreads.[150] Persons should also be aware that Mexican-style cheeses made from pasteurized milk (e.g., queso fresco) likely contaminated during cheese making have caused *Listeria* infections.[150] Honey should not be fed to infants younger than 1 year of age because of the risk of infant botulism.

The risk of waterborne disease can be minimized by appropriate drinking water treatment, routine inspections of private wells, and proper hygiene, particularly at childcare facilities and recreational water venues such as pools and beaches. The risk of enteric illnesses caused by recreational water exposures can be reduced by the following means: adequate training of pool operators and enforcement of pool codes through pool inspections; provision of appropriate hygiene infrastructure, such as conveniently placed, well-stocked, and well-maintained showers, toilets, diapering stations, and handwashing facilities at recreational water venues; and public education. Persons with diarrhea, including aquatics staff members, should not swim or participate in water play; all others should shower with soap immediately before entering the water and should wash hands thoroughly after using the toilet or changing diapers. The CDC also recommends checking diapers every 30 to 60 minutes while children are swimming to help prevent fecal contamination of the water. Diapered children should be changed at a diapering station (not at the poolside). Children should be taught not to swallow water while swimming or playing at splash parks. Limiting water play in childcare facilities may also reduce the risk of enteric disease.[151] Additional information is available at www.cdc.gov/healthywater/swimming/.

Much of foodborne and waterborne illness prevention lies in reducing contamination of food and water before it reaches the consumer. Major revision of meat and poultry inspection regulations and procedures and revised requirements for drinking water treatment began in the US in the 1990s. For food and water that still may be contaminated with dangerous pathogens, a systematic disinfection or pathogen reduction step, such as pasteurization of milk and chlorination of water, is required. Meats, seeds for sprouting, spices, shell eggs, and some produce items may also be irradiated before sale in commercial markets in the US. Such regulatory and industry efforts have been successful in decreasing the incidence of infection with several foodborne pathogens. For example, the incidence of *E. coli* O157 and *Salmonella enteritidis* serotype Typhimurium infections was significantly lower in 2014 than during 2006 to 2008.[152] Similarly, Environmental Protection Agency regulations that protect public water supplies, such as the Surface Water Treatment Rule, coincide with a decrease in the proportion of drinking water outbreaks associated with public water systems and surface water supplies.[75] However, foodborne and waterborne illnesses remain important public health concerns.

Clinicians have the important role of providing education and appropriate counseling to high-risk patients, including parents of infants and young children and persons with immunocompromising conditions, about the health hazards of food and waterborne pathogens, vehicles of transmission, and prevention measures.

Zoonotic Exposures

Clinicians should educate individual patients and families about the potential for animals to serve as a source of enteric illness in humans. Many animals carry enteric pathogens but appear healthy. Zoonotic enteric infections can be prevented through careful hand and environmental hygiene and by limiting interaction of some populations with animals and their environments. Children <5 years of age, older adults, and persons with immunocompromising conditions should avoid contact with turtles and other reptiles, amphibians, baby poultry, rodents, farm animals, and animal-derived pet treats and pet foods.[84,85,153] Children should not be allowed to kiss animals or to put their hands or other objects into their mouths while interacting with animals. Pets and other animals should be kept outside areas where food is prepared, stored, or served. Animal habitats and equipment used to care for animals should be cleaned outside the home to reduce the risk of cross-contamination. Careful handwashing with soap and water as soon as possible after contact with animals, their feces, their cages or pens, and their food can help prevent infection. Additional information is available at www.cdc.gov/healthypets/.

Acute Hepatitis

Vahe Badalyan, Laurie S. Conklin, John D. Snyder [†]

Acute hepatic inflammation in children can have many infectious and noninfectious causes (Table 60.1). Acute liver injury of various causes results in a limited number of clinical manifestations and findings. This chapter covers the evaluation and diagnosis of acute liver injury in immunocompetent children. The pathogenesis of many infectious causes is covered more fully in pathogen-specific chapters.

TABLE 60.1

Age of Onset of Infectious and Noninfectious Causes of Acute Hepatitis

Etiology	Age of Presentation		
	Neonates and Infants	**Children**	**Adolescents**
INFECTIOUS			
Primarily Hepatotropic			
Hepatitis A	−	+	+
Hepatitis B	+	+	+
Hepatitis C	+	+	+

+, recognized or usual age of occurrence; −, unexpected or not an age of occurrence.

Approach to Evaluation and Diagnosis

Signs and symptoms associated with acute hepatic injury usually include jaundice, vomiting, poor feeding, lethargy, hepatomegaly, and right upper quadrant pain. Assessment of the multiple possible causes begins with the patient's age and a detailed history and physical examination, with special emphasis on potential exposures, evolution of symptoms, concomitant health problems, and family history. The physical examination must include a careful evaluation for extrahepatic manifestations of disease, as well as a thorough assessment of the abdomen.

Elevated serum hepatic enzyme levels, and often elevated bilirubin levels, are present in people with acute hepatitis, but the pattern of elevations rarely is diagnostic.[1–3] In most cases, an initial core set of tests, common to all age groups, is ordered simultaneously to provide a complete initial assessment of the disease process (Box 60.1). Hepatitis virus infection should be suspected in patients with predominant or severe hepatocellular dysfunction and in fulminant hepatitis. The evaluation for infectious causes of hepatitis in children relies on serologic tests to identify antibodies (usually immunoglobulin M) or antigens or the use of molecular diagnostic techniques, especially polymerase chain reaction, to diagnose infection.[1–6] Additional tests are considered individually, depending on the child's age and exposures (Table 60.2). For example, neonates are not evaluated for hepatitis A, D, E, or G except in unusual circumstances. Rubella testing rarely is required because maternal testing is included in routine prenatal care. The TORCH (*Toxoplasma*, other, rubella, cytomegalovirus (CMV), and herpes simplex virus [HSV]) serologic screen is inappropriate because certain agents (*Toxoplasma* and rubella virus) are unlikely to cause hepatitis as a cardinal feature and CMV and HSV infection are optimally diagnosed by other techniques.[3,6] Liver biopsy rarely is required to make the diagnosis of infectious hepatitis. The severity of the child's illness can influence the pace and extent of testing. For example, in a mildly affected child, results of tests for infectious diseases often are evaluated before metabolic disorders are pursued.

Box 60.1

Initial Diagnostic Evaluation for Suspected Hepatitis in All Age Groups

Blood

Tests of hepatic cell injury and function

Bilirubin, total and direct

Alanine aminotransferase

Aspartate aminotransferase

γ-Glutamyltranspeptidase

Albumin

Prothrombin time

Ammonia

Fasting glucose

Tests for infectious causes

Serologic tests for hepatotropic viruses (see Table 60.2)

Serologic tests for Epstein-Barr virus

Serologic, antigen, or molecular tests for cytomegalovirus

Serologic or molecular tests for human immunodeficiency virus

Metabolic screening lists

α_1-Antitrypsin level and protease inhibitor type

Urine

Shell vial culture for cytomegalovirus

Radiology

Liver and biliary ultrasound examination

TABLE 60.2

Additional Age-Specific Evaluation for Patients With Suspected Hepatitis

	Age Group		
	Neonates	**Children**	**Adolescents**
BLOOD TESTS			
Infectious	HBsAg Anti-HBc IgM Anti-HCV, HCV PCR Toxoplasmosis titer: mother and child Plasma HSV PCR, virus culture mucosal strips Plasma enterovirus PCR, virus culture mucosal samples	HBsAg	HBsAg
		Anti-HBc IgM	Anti-HBc IgM
		Anti-HAV IgM	Anti-HAV IgM
		Anti-HCV, HCV PCR	Anti-HCV, HCV PCR
		Anti-HCV	Anti-HCV
		Anti-HDV	Anti-HDV
		Anti-HEV (if travel history)	Anti-HEV (if travel history)
Metabolic	Cystic fibrosis screen or sweat test, serum amino acids	Same as for neonates	Same as for neonates
		Ceruloplasmin	Ceruloplasmin
		24-hr urine copper	24-hr urine copper
Autoimmune		ESR, quantification of serum immunoglobulins; antinuclear antibody; LKM and smooth-muscle antibodies	Same as for children
URINE TESTS			
Metabolic	Reducing substances; organic acid screen	Same as for infants	

anti-HBc IgM, hepatitis B core immunoglobulin M antibodies; ESR, erythrocyte sedimentation rate; HAV, hepatitis A virus; HBsAg, hepatitis B surface antigen; HCV, hepatitis C virus; HDV, hepatitis D virus; HEV, hepatitis E virus; HSV, herpes simplex virus; LKM, liver-kidney-microsomal; PCR, polymerase chain reaction.

The diagnosis of most anatomic lesions is made by ultrasound examination (e.g., choledochal cyst) or liver biopsy (e.g., intrahepatic cholestasis, congenital hepatic fibrosis, and sclerosing cholangitis).[1–3] Endoscopic retrograde cholangiopancreatography and magnetic resonance cholangiopancreatography may be helpful in diagnosing biliary tract lesions, especially in older children.[1–3]

Infectious Causes

Neonatal Hepatitis

Hepatitis in neonates caused by specific agents usually is distinguished from the category of neonatal hepatitis, which has been used to designate hepatic inflammation of no known cause.

The 6 hepatotropic viruses (i.e., hepatitis A, B, C, D, E, and G viruses [HAV, HBV, HCV, HDV, HEV, and HGV, respectively]) play a limited role in symptomatic hepatitis in neonates. However, various other infectious agents have been implicated in hepatic inflammation in neonates.[3–6] HSV and enterovirus can cause liver necrosis, coagulopathy, and a fulminant sepsis–like syndrome.[9–11] Congenital viral infections cause milder hepatitis and often are associated with prematurity and growth retardation; rubella virus is associated with congenital malformations.[3,6] Other causes of disseminated infection and associated hepatitis in neonates include congenital syphilis, disseminated candidiasis, and toxoplasmosis.[3,5] Infection caused by the agents of these disorders can involve skin, central nervous, cardiorespiratory, and musculoskeletal systems.[3,5]

Disseminated Infections

Disseminated systemic and extrahepatic infections must be considered when jaundice is present, especially in the newborn infant.[5,6] Gram-negative bacterial infections, disseminated HSV infections, and enterovirus infections are important causes in neonates that require immediate, appropriate therapy.[7,8] The pathogenesis of hepatic dysfunction in sepsis is not understood completely, but the cholestatic effects of endotoxins and endotoxin-induced mediators appear to be important.[7,8] Jaundice also can occur in the absence of severe illness, as in gram-negative bacillary urinary tract infection.[7] Disseminated infection caused by gram-positive organisms and viruses also can be associated with cholestasis.[8] The diagnosis usually is made because infected children appear severely ill. A clue to diagnosis is an elevation of serum levels of conjugated bilirubin greatly out of proportion to elevation of aminotransferases or alkaline phosphatase.[4] In the absence of hemolysis associated with mild liver disease, this pattern suggests septicemia.

Other viruses that can cause hepatic injury as part of a disseminated, multisystem illness include Epstein-Barr virus, cytomegalovirus, adenoviruses, rubella, and human immunodeficiency virus (HIV)[3,5,6] The resulting hepatic dysfunction ranges from mild to fulminant disease. Fulminant hepatitis is characterized by rapid progression to high hepatic enzyme levels, decreased production of coagulation proteins, elevated ammonia, hypoglycemia from loss of glycogen reserves, shock, coma, or death.

Hepatitis Viruses

Hepatitis a Virus.

HAV infection continues to be the most common cause of acute hepatitis reported in the United States.[12,13] Infection primarily is spread through direct human fecal-oral contamination or by contaminated food and water.[13,14] HAV is common in early childhood, especially in developing countries with poor conditions of sanitation and hygiene. Almost all children in these countries become seropositive before 5 years of age.[12,14] In the US, transmission often occurs in childcare facilities, but with inclusion of hepatitis A vaccine in the childhood immunization schedule in the US, a significant decrease in rates of disease has occurred.[6,13,14] Illness usually is mild in young children and often manifests with symptoms of an influenza-like illness.[6,12,14] Outbreaks in childcare facilities are recognized usually by illnesses with jaundice in staff members or parents of attendees (see Chapter 3).

Hepatitis B Virus.

HBV is the only hepatotropic virus that is not directly cytopathic; it causes disease through the host's immune response against virus-infected hepatocytes. The severity of infection is inversely related to the effectiveness of the immune system to diminish viral replication.[15] Two main patterns of transmission occur. In endemic areas such as China, Southeast Asia, and sub-Saharan Africa, transmission usually occurs by vertical transmission at birth or through horizontal transmission among children <5 years of age.[15,16] In the US, the most common routes of transmission are injection drug use, sexual contact, and nosocomial infection; no risk factor is found in approximately 30% of cases.[13,15–17] The incidence of HBV infections in neonates is declining in countries with neonatal immunization programs.[15–17] Most neonatal infections are not associated with clinically evident disease, but chronic infection develops in infants not treated immediately after birth with hepatitis B immune globulin and vaccine.[15–17] Children and adolescents are more likely to develop clinical illness if they are infected with HBV, usually acquired by close contact with an infected adult, sexual contact, or use of intravenous drugs.[15–17] Viral genotypes are important predictors of clinical outcome, drug responses, and mutations.[15] Implementation of a national vaccination strategy to eliminate HBV transmission has greatly reduced the disease burden in the US, but elimination will require an effective vaccination program for several generations, including vaccination of at-risk adults.[13,15–19] In the US, interferon α and oral agents including lamivudine (3 years and older), adefovir and tenofovir (12 years and older) and entecavir and telbivudine (16 years and older) have been approved by the Food and Drug Administration (FDA) for use in children with chronic HBV.[20,21]

Hepatitis C Virus.

HCV infection in young children is acquired primarily by perinatal transmission in the US, but unsafe injections and unsafe medical procedures are important causes in resource-poor countries.[22] In older people, most cases are caused by injection drug use or sexual contact with an infected partner.[22] Because of major improvements in serologic diagnosis, HCV infection now is rarely caused by blood transfusion or organ transplantation. In contrast to HAV and HBV, no effective HCV vaccine is available.[22] The efficiency of perinatal transmission appears to be low in the general population but greatly increases if the mother is coinfected with HIV or has a high titer of HCV RNA.[22,23] HCV infections usually are mild or asymptomatic in children, but in many infected children, disease progresses, and fibrosis, cirrhosis, and hepatocellular cancer develop.[22,23]

Until recently, the standard HCV treatment in adults was a combination regimen of pegylated interferon α with ribavirin.[23] This combination was shown to be effective in randomized trials in children and is approved by the FDA for use in children ≥3 years of age.[23] The emergence of interferon-free, all-oral regimens involving direct-acting antiviral agents (e.g., sofosbuvir, simeprevir, and ledipasvir) revolutionized the therapy of chronic HCV, with a greater than 90% sustained viral response rate and an excellent safety profile.[24] Multicenter clinical trials using combinations of these agents in children with chronic HCV are under way.[24]

Hepatitis D Virus (Delta Virus).

HDV infection, which can occur only in conjunction with HBV infection, has been described rarely in neonates; the importance of perinatal transmission appears to be minimal.[25] In older infants and children, the disease is uncommon and usually occurs in people with chronic HBV infection.[25]

Hepatitis E Virus.

HEV is common in endemic areas of developing countries and in travelers to those areas, especially the Middle East and Asia. However, autochthonous (locally acquired) HEV infection also is emerging in industrialized countries, where HEV is thought to be a zoonosis transmitted by pigs.[26] HEV has not been reported as a cause of neonatal hepatitis.[27] However, pregnant women with jaundice and acute viral hepatitis caused by HEV infection have a higher mortality rate and worse obstetric and fetal outcomes than do pregnant women with other types of viral hepatitis.[28] HEV disease is similar to HAV infection, except that HEV primarily affects older children and adults and has been associated with neurologic disorders.[26,29] An HEV vaccine has been shown to be safe and effective in phase III trials.[30]

Hepatitis G Virus.

HGV, the most recently identified hepatitis virus, appears to produce the mildest illness of the hepatotropic viruses.[31] Although most infected people have evidence of persistent viremia, histologic evidence of HGV infection is rare, and serum aminotransferase values usually are normal. Currently, no conclusive evidence indicates that HGV causes fulminant or chronic disease, and it appears that HGV may not be a pathogen.[31]

Anatomic Causes

Biliary Atresia.

Biliary atresia is the most common cause of neonatal cholestasis and usually is manifest by 1 month of life.[32] Biliary atresia is a process affecting both intrahepatic and extrahepatic ducts that leads to ongoing fibrosis and eventual obliteration of the biliary tract. Even in children who are treated surgically, this process eventually progresses to cirrhosis.[32] Although no clinical or laboratory findings are diagnostic of biliary atresia, most infants are healthy and well grown at birth and are asymptomatic for the first several weeks of life.[1–3,32] Bilirubin levels then rise, along with mild to moderate increases of alanine aminotransferase and aspartate aminotransferase, and a disproportional increase of γ-glutamyltranspeptidase.[32] By contrast, infants with neonatal infections are more likely to be born prematurely, small for gestational age, and ill-appearing at birth.[1–3] The finding of acholic stools, hepatosplenomegaly, situs inversus, splenic abnormalities, and congenital cardiac defects associated with cholestasis should suggest the possibility of biliary atresia.[33]

Paucity of Bile Ducts.

Paucity of bile ducts is a histologic diagnosis made when the ratio of ducts to portal tracts is less than 1.[34] Paucity of bile ducts can be grouped into syndromic or nonsyndromic varieties; both usually are manifest in infancy with jaundice and hepatomegaly. Children with the syndromic type (Alagille syndrome) have a variety of associated anomalies including peculiar facies (broad forehead, hypertelorism, small chin) and cardiac (most commonly peripheral pulmonic stenosis), ocular (posterior embryotoxon), and vertebral arch (butterfly vertebrae) abnormalities.[34] The nonsyndromic form of paucity of bile ducts does not include such anomalies.[34]

Choledochal Cysts.

Choledochal cysts often manifest in infancy but can become symptomatic in any age group.[35] The spectrum of disease ranges from solitary lesions involving the extrahepatic biliary tree to diffuse intrahepatic involvement (Caroli disease).[35] Infants present with jaundice, elevated liver enzymes, and an abdominal mass.

Congenital Hepatic Fibrosis.

Congenital hepatic fibrosis, a syndrome that includes hepatomegaly, cholestasis, cystic disease of the kidneys, and portal hypertension, varies in clinical manifestation depending on the age of the child.[36] The renal form of disease (autosomal recessive polycystic disease) usually predominates in infancy, whereas the hepatic-related form is more common in older children and adults.[36]

Genetic Intrahepatic Cholestasis.

Several forms of genetic intrahepatic cholestasis have been identified in which molecular defects can lead to abnormalities in bile synthesis, transport, and excretion.[37] The most common presentation is jaundice in neonates; pruritus is often reported in older children.[37] Some diseases, such as bile salt export pump abnormalities and multidrug resistance protein 3 (MDR3) deficiency, are liver-specific disorders. Others, such as progressive familial intrahepatic cholestasis, are systemic disorders with multisystem involvement.[38]

Autoimmune Causes

Autoimmune Hepatitis.

Autoimmune hepatitis is a progressive, immune-mediated inflammatory disorder of the liver that may mimic acute viral hepatitis.[39–41] Autoimmune hepatitis usually manifests with the insidious onset of malaise, anorexia, headache, fatigue, and jaundice in adolescents, with a striking female predominance (see Chapter 61). However, the disease can occur in younger children, in both sexes, and with acute manifestations precipitated by another event, such as an intercurrent viral illness.[39–41] The diagnosis of autoimmune hepatitis is made using the clinical and serologic criteria included in a scoring system developed by a group of experts.[41] The constellation of findings in autoimmune hepatitis includes elevated aminotransferases, hypergammaglobulinemia, elevated serum autoantibodies, (smooth muscle antibody [SMA] in type 1 autoimmune hepatitis, anti-LKM [liver-kidney-microsomal]–

1 in type 2 autoimmune hepatitis, and antinuclear antibody [ANA] in both types), and evidence of other disorders known to be associated with disturbances in immunoregulation.[39–41]

Primary Sclerosing Cholangitis.

Primary sclerosing cholangitis is a chronic immune-mediated inflammation of bile ducts that results in progressive fibrosis of the intrahepatic and extrahepatic bile ducts, cholestasis, cirrhosis, and portal hypertension.[42,43] It is rare in young children and usually manifests in adolescence or adult life.[43] Many patients may be asymptomatic at the time of diagnosis and have incidental findings of abnormal serum liver enzymes or intrahepatic bile duct dilatation on cross-sectional imaging.[42,43] In symptomatic patients, jaundice, pruritus, right upper quadrant pain, and fatigue are the most common signs. The disease often is associated with inflammatory bowel disease, especially ulcerative colitis or Crohn colitis.[44] Patients with primary sclerosing cholangitis are at risk for developing associated cholangiocarcinoma.[42,43]

Metabolic Causes

Metabolic conditions include a large group of disorders that must be considered in every infant with hepatitis, especially children in whom usual infectious causes have been excluded.[1–3,45] Initial manifestations including jaundice, lethargy, vomiting, hepatomegaly, and failure to thrive, mimicking many other causes of hepatic dysfunction. Developmental delay can be an important clue to metabolic disease. Many of the metabolic diseases occur in early childhood, so extensive testing for these disorders usually is not required when previously healthy children and adolescents present with hepatic dysfunction.

α_1-Antitrypsin Deficiency.

α_1-Antitrypsin deficiency can cause a hepatitis-like illness in children of any age group, including neonates.[46] Approximately 10% to 20% of people with α_1-antitrypsin deficiency develop signs and symptoms of liver dysfunction at some time.[46,47] Neonatal liver disease usually is limited to infants with homozygous protease inhibitor phenotype ZZ.[46,47] The clinical presentation is not distinctive; infants may present with cholestatic jaundice, poor feeding, poor weight gain, hepatomegaly, elevated aminotransferases, hypoalbuminemia, or coagulopathy.[46,47] Disease should be considered in any infant, child, or adolescent with jaundice or abnormal liver function test results. The condition frequently is unmasked by an intercurrent infection or a hepatic insult.[46,47]

Cystic Fibrosis.

Cystic fibrosis is associated with a wide range of hepatobiliary tract diseases, including steatosis, focal biliary cirrhosis, cholelithiasis, and intrahepatic duct stones or sludge.[48,49] Clinically significant hepatobiliary tract disease occurs in approximately one third of children with cystic fibrosis, but it accounts for only approximately 2% to 3% of deaths.[48,49] In the neonatal period, severe cholestatic disease can occur in the absence of pulmonary involvement. The gold standard test for diagnosis remains the sweat test.[48,49] However, serologic genetic screening can be helpful in suspected patients of European descent because they often have the most common mutations, including δ-F508.[48,49] If the genetic screening result is negative, a sweat test still is required to rule out the diagnosis. Genetic screening can be especially valuable in neonates, in whom a sweat test often is unreliable because of difficulties in obtaining an adequate sample. Given the lack of phenotypic association between the incidence of liver disease and specific mutations, genetic testing cannot be used to predict the development of liver disease.[49]

Carbohydrate Metabolism Disorders.

Several disorders of carbohydrate metabolism can cause hepatic dysfunction in infants and children.[50] A family history of liver disease should be sought because disorders of carbohydrate metabolism are inherited, and the pattern of symptom onset can help to guide the diagnosis. For example, the onset of diarrhea and liver dysfunction occurring after ingestion of fructose (e.g., in fruit juices) raises the likelihood of fructosemia. Galactosemia must be screened for by testing the urine for reducing substances in any neonate with liver dysfunction who receives lactose.[50] In addition, fasting hypoglycemia, in the absence of liver failure or end-stage hepatic disease, is an important clue to the possibility of disorders of carbohydrate metabolism, including 6 of the 8 forms of glycogen storage disease.[51] Splenomegaly is not common in these disorders and usually occurs only in amylopectinosis disease (type IV glycogen storage disease).[50]

Protein Metabolism Disorders.

Disorders of protein metabolism often manifest in infancy, but some diseases, such as the chronic form of tyrosinemia, can occur later in life.[52] Developmental delay and seizures often are associated with these disorders, but they may not be manifest initially; laboratory evaluation or biopsy may be required to establish the diagnosis.[53] Hyperammonemia can be an important clue to disorders involving protein metabolism, including disorders of the urea cycle and organic acidemias.[52,53] Many of these disorders are apparent at birth or shortly thereafter.

Metal Metabolism Disorders.

Consideration of disorders of metal metabolism is influenced by the age of the child. For example, Wilson disease, which can cause acute, chronic, or fulminant liver dysfunction, rarely manifests in children <4 years of age.[54,55] By contrast, Indian childhood cirrhosis typically occurs in children <3 years of age, and hepatic insufficiency develops in the first week of life in neonatal hemochromatosis.[55]

Lipid Storage Diseases.

The lipid storage diseases usually are associated with hepatosplenomegaly and progressive central nervous system deterioration. Signs and symptoms can be apparent early in the first year and can progress quickly to death (Wolman disease), or the onset can occur throughout childhood and even into adulthood (Niemann-Pick and Gaucher diseases).[56]

Disorders of Mitochondrial Fatty Acid Oxidation.

Growing numbers of disorders of fatty acid oxidation are being discovered. Children with these disorders can present in infancy but often do not develop symptoms until later in life, when prolonged fasting, often in conjunction with an acute infection, causes a Reye-like syndrome.[57] Cardinal features include hypoglycemia, acidosis, and hepatic injury, often with little elevation in bilirubin levels.

Disorders of Bile Acid Metabolism.

Increasing numbers of disorders that cause errors in metabolism of bile acids are being discovered; these disorders routinely cause cholestasis and hepatitis in neonates.[58] These rare disorders previously were placed in the category of neonatal or idiopathic hepatitis. Clinical manifestations usually are not diagnostic, but infants often have low serum bile acids, low γ-glutamyltranspeptidase levels, and no pruritus, findings that are otherwise rare in conditions of hepatic dysfunction and chronic cholestasis.[58,59]

Toxins and Medications

Various hepatotoxins, including medications and chemicals, can be associated with a hepatitis-like picture.[60,61] The clinician should obtain a history of exposure to medications including acetaminophen, valproic acid, tegretol, isoniazid, sulfonamides, phenytoin, carbamazine, and phenobarbital. Drug-related hepatitis in neonates is rare, but exposure to these compounds must be considered in older infants and children because the diagnosis usually is made on clinical grounds.[60,61] Children receiving total parenteral nutrition, especially prematurely born infants, are at risk of developing hepatic injury.[61] Given that no diagnostic test is available for this disorder, it must be considered as a diagnosis of exclusion following rigorous evaluation. A rare but important toxic cause of severe hepatic injury in children is ingestion of *Amanita* mushrooms.

Tumors

Hepatic tumors can manifest with hepatomegaly and abnormal serum hepatic tests but usually are identified by initial imaging studies. The liver usually feels hard on palpation.

Idiopathic Causes

Age helps in differentiating disorders in the idiopathic category. Neonatal hepatitis (also called giant cell hepatitis) is defined as a group of disorders of unknown origin that are associated with cholestasis in the neonate and young infant.[62] The presentation can be similar to that of biliary atresia but usually is distinct from neonatal infectious hepatitis, which is characteristically part of an illness affecting multiple organ systems.

Chronic Hepatitis

Parvathi Mohan, Muhammad Ali Khan, John D. Snyder [†]

Chronic hepatitis is a clinical and pathologic syndrome associated with a wide variety of diseases and conditions (Table 61.1).[1,2] Chronic hepatitis typically is defined as ongoing injury with inflammation lasting ≥6 months. However, the impact of inflammation can vary greatly, so a combination of clinical, laboratory, and histologic findings now is sought that can establish the diagnosis sooner and enable earlier treatment.[1–3]

TABLE 61.1

Causes of Chronic Hepatitis by Age of Onset

Causative Factor	Age of Onset		
	Neonates, Infants	**Children**	**Adolescents**
HEPATOTROPIC INFECTION			
Hepatitis B virus	+	+	+
Hepatitis C virus	+	+	+
Hepatitis D virus	+	+	+
GENERALIZED INFECTION			
Cytomegalovirus	+	+	+
Epstein-Barr virus	+	+	+
Human immunodeficiency virus	+	+	+
Rubella virus	+	−	−
Varicella virus	+	+	+
ANATOMIC ABNORMALITIES

TOXINS AND DRUGS	+	+	+
IDIOPATHIC CONDITIONS			
Cryptogenic	+	+	+
Neonatal hepatitis	+	−	−

+, recognized or usual age of occurrence; −, unexpected age or never an age of occurrence.

Approach to Evaluation

A careful history and physical examination are important and can be challenging because the onset often is insidious and many patients are asymptomatic.[3] Signs and symptoms, when present, are variable and can include hepatitis, fatigue, abdominal pain, anorexia, weight loss, dark urine, clay-colored stools, and fever.[1–3] Some patients may receive a diagnosis after months or years of puzzling symptoms such as relapsing jaundice. Alternatively, variceal bleeding or organomegaly can be the presenting sign. A history of exposure to blood products, use of intravenous drugs, and maternal infection are important clues to viral hepatitides.[1–3] The presence of thyroiditis, Sjögren syndrome, or idiopathic colitis, especially in a female patient, raises the possibility of autoimmune hepatitis (AIH).[3,4] A history of exposure to drugs and toxins also must be sought.

The pattern of biochemical abnormalities usually is not diagnostic for a specific cause. Serum levels of serum aminotransferases often are elevated but can be intermittently normal in hepatitis C virus (HCV) infection.[5] Levels of serum aminotransferases often do not reflect the severity of disease identified by liver biopsy, and patients can progress to cirrhosis with normal aminotransferase levels.[1–3,5] Bilirubin elevations and levels of other serum enzymes, such as alkaline phosphatase and γ-glutamyltranspeptidase, can be variable.

In contrast to acute hepatitis, liver biopsy often is an essential tool in the diagnosis and management of patients with chronic hepatitis. Liver biopsy also is used to assess prognosis by grading the severity of disease and its progression. The terms *chronic active hepatitis,* *chronic persistent hepatitis*, and *chronic lobular hepatitis* have been replaced by newer terminology that grades the severity of liver inflammation and fibrosis from minimal to severe.[1–3]

Infectious causes are most common and should be included in the initial evaluation (Box 61.1; see Table 61.1). If results of initial testing are negative, further evaluation is warranted.[2,3]

Box 61.1

Laboratory Evaluation of Children With Chronic Hepatitis

Initial Tests

Blood

Tests of hepatic injury and function

- Bilirubin, total and direct
- Alanine aminotransferase
- Aspartate aminotransferase
- Alkaline phosphatase or γ-glutamyltranspeptidase
- Total protein and albumin
- Prothrombin time
- Fibrinogen
- Ammonia
- Fasting glucose
- Platelet count
- Serum iron and ferritin

Tests for infectious agents

- Hepatitis B virus surface antigen and core antibody
- Hepatitis C virus antibody
- Hepatitis D virus antibody
- Epstein-Barr virus antibody
- Cytomegalovirus antibody
- Human immunodeficiency virus antibody

Urine

Shell vial culture for cytomegalovirus for neonates

Imaging

Ultrasonography of the liver

Further Evaluations if Test Results for Infectious Causes Are Negative

Blood

Erythrocyte sedimentation rate

Quantitative serum immunoglobulin levels

Antitissue transglutaminase and serum immunoglobulin A level

Autoantibody tests

- Antinuclear antibody
- Liver-kidney-microsomal antibody

- Anti–smooth muscle antibody
- P-antinuclear cytoplasmic antibody

Metabolic tests

- α_1-Antitrypsin level with protease inhibitor type
- Ceruloplasmin level

Sweat test

Urine

Quantification of copper in 24-hour specimen

Radiology

Magnetic resonance imaging

Liver Biopsy

Etiologic Factors

Infectious Causes

Hepatitis B virus (HBV) infection is one of the most common causes of chronic hepatitis in children worldwide, but the incidence has decreased substantially in the United States as a result of universal vaccination and blood donor screening.[6] Chronic HBV infection still is encountered in US children infected perinatally or adoptees from endemic areas.[2,6] The risk of developing chronic HBV infection is related directly to the age of acquisition. Perinatal infection is associated with a 90% to 95% risk of chronic hepatitis in infants born to mothers who are hepatitis B e antigen (HBeAg) positive, whereas infection in adults results in a <10% incidence of chronic hepatitis.[2,6] Exposure to infected blood products, intravenous drug use, and institutionalized settings increase the risk of HBV infection and subsequent chronic hepatitis.[6,7] Hepatitis D virus (HDV) is an incomplete virus that occurs only in conjunction with HBV infections. Perinatal transmission is rare, and most cases of HDV infection occur as superinfections in patients who are longterm carriers of HBV, thus leading to more severe hepatitis.[8] The signs and symptoms of chronic HBV infection are variable; many children are asymptomatic or have mild disease.[6,7] The diagnosis usually is made based on serologic criteria; a liver biopsy is performed primarily for prognosis or evaluation of therapy.[3,7] Most children remain immune tolerant until late childhood or adolescence, and they do not respond well to currently available treatment. Spontaneous HBeAg clearance occurs in only 1% to 5% of children infected in utero (vertical transmission) but in 70% to 80% of children infected after birth (horizontal transmission).[9] The US Food and Drug Administration has approved interferon α and oral agents for use in children with chronic HBV; approved oral agents include lamivudine (for children ≥3 years of age), adefovir and tenofovir (≥12 years), and entecavir and telbivudine (≥16 years).[9,10] The rate of viral clearance is still low with these therapies, and interferon is associated with significant adverse effects, whereas viral resistance and relapse are commonly seen with the oral agents; therefore, routine treatment of immune tolerant children or carriers is not warranted.[9]

HCV has emerged as a leading cause of chronic hepatitis in adults in the US, but the estimated seroprevalence of HCV antibodies in children is approximately 0.6%.[5] Before the advent of effective screening techniques in the early 1990s, children who had received blood products were at greatest risk for infection. Now most new pediatric cases are caused by vertical transmission, with a 5% to 7% risk of infection in infants born to seropositive mothers.[5,11] Risk factors for transmission include maternal coinfection with human immunodeficiency virus, high maternal HCV viral load, prolonged rupture of membranes, and fetal anoxia. Breastfeeding is not contraindicated, except in the presence of bleeding from the nipple or mastitis.[5] The diagnosis usually is made by detection of antibodies to core and nonstructural antigens, but detection of active infection is best established by polymerase chain reaction. Confirmatory testing should be performed after the first year of life because transient viremia has been observed in neonates.[5,11] Serum aminotransferase values can fluctuate in chronic HCV infection, and liver biopsy often is performed to assess the severity of liver disease or evaluate the efficacy of antiviral therapies.[5,11] The natural history of chronic HCV may be affected by several factors such as genotype, comorbidity with other viral infections, cancer, intravenous drug use, and obesity.[5] Infants infected at birth may clear the infection spontaneously, usually within the first 2 years but occasionally as late as 7 years.[5] Progression of the disease appears to be slower in children than in adults, although advanced fibrosis, cirrhosis, and hepatocellular carcinoma can be encountered in chronically infected children.[11] Treatment of chronic HCV infection has been revolutionized with the emergence of interferon-free, all-oral regimens using direct-acting antiviral agents such as sofosbuvir, simeprevir, and ledipasvir.[12–14] These regimens have been highly successful against all genotypes and have demonstrated excellent sustained viral response and safety profiles.[13,14] Multicenter clinical trials using combinations of these agents in children are just starting.

Cytomegalovirus, Epstein-Barr virus, and other viruses can cause chronic hepatitis, although progression of these infections to cirrhosis and liver failure is rare (see Table 61.1).[2]

Nonalcoholic Fatty Liver Disease

Nonalcoholic fatty liver disease (NAFLD) refers to a spectrum of conditions associated with fatty infiltration of the liver. Findings range from simple fatty infiltration to nonalcoholic steatohepatitis, which can progress to advanced liver disease and cirrhosis.[15,16] NAFLD is the most common cause of chronic liver disease in pediatrics, with an estimated prevalence of 3% to 10% in all children and as high as 70% to 80% in obese children.[15,16] Patients often are asymptomatic and come to attention when elevated aminotransferase levels are noted incidentally. Physical examination usually is remarkable only for excess weight (body mass index >85% for age) and hepatomegaly.[15,16] Acanthosis nigricans also may be present as a sign of associated insulin resistance. Several factors are implicated in development of NAFLD, including hyperinsulinemia, insulin resistance, associated free fatty acid hepatotoxicity, genetic predisposition, the intestinal microbiota, gut-derived inflammatory mediators, and oxidant stress.[16] Sonography demonstrates a homogeneous pattern of increased liver echogenicity; magnetic resonance imaging is considered to be a more specific diagnostic modality.[16] An extensive workup, often including liver biopsy, may be required to confirm the diagnosis and exclude other causes of liver disease.[15,16] Hepatic dysfunction usually normalizes if the body mass index is improved with a low-glycemic diet and exercise. Pharmacologic agents have been studied, and the use of vitamin E has been associated with improvements in histopathologic features but not in aminotransferase levels.[17] Insulin-sensitizing agents, such as metformin, have not been shown to be effective.[17]

Autoimmune and Autoinflammatory Disorders

Autoimmune liver disease is a heterogeneous group of diseases consisting of AIH, primary sclerosing cholangitis, and primary biliary cirrhosis.[18,19] AIH causes a diffuse pattern of hepatocellular injury. Primary sclerosing cholangitis and primary biliary cirrhosis involve injury to the biliary tract with secondary cholestasis and hepatocyte injury leading to acute liver failure or cirrhosis, if untreated.

AIH mostly occurs in children <18 years of age; the mean age of onset is 6 to 10 years, but the disease has been diagnosed in children as young as 6 months of age.[1,18] AIH should be considered in patients with the following findings: female sex, coexistent autoimmune disease, low ratio of albumin to total protein, elevated immunoglobulins, and relative elevation of serum aminotransferases compared with alkaline phosphatase.[19] In addition, elevated titers of non–organ-specific autoantibodies are characteristic of AIH and are used to identify subgroups of disease. In type 1 AIH, antinuclear antibodies, anti–smooth muscle antibodies, or antiactin antibodies usually are present; in type 2 AIH, anti–liver-kidney-microsomal antibodies or anticytosol antibodies are usually seen.[1,3,18] Although clinical, laboratory, and histologic findings are helpful in suggesting the diagnosis, no single diagnostic test exists for AIH, and exclusion of infectious, toxic, and metabolic causes is critical. Autoantibody-negative AIH also has been reported.[18,19] Liver biopsy may be diagnostic. Treatment usually involves the use of corticosteroids initially, followed by longterm immunomodulator therapy, such as with azathioprine. More recently, budesonide has been used to try to induce disease remission.[20] In some cases, immunosuppressive agents such as cyclosporine, mycophenolate, or tacrolimus have been used.[18,19] Liver transplantation may be required but can be complicated by recurrence of AIH in the transplanted liver.[18,19]

Primary sclerosing cholangitis is a rare cause of chronic liver disease in children and adolescents and often is associated with inflammatory bowel disease.[21,22] It is characterized by progressive fibrosis obliterating the intrahepatic and extrahepatic bile ducts.[21] The presence of jaundice, fatigue, and right upper quadrant pain is the most common presentation.[21,22] The diagnosis often requires endoscopic retrograde cholangiopancreatography and liver biopsy. However, continuing improvements in magnetic resonance cholangiopancreatography may allow this technique to supplant the use of more invasive procedures.[21,22] Treatment with ursodeoxycholic acid and immunosuppressive agents can improve laboratory test results, but it usually does not improve symptoms or affect longterm survival.[21,22] Many patients ultimately require liver transplantation but transplantation is associated with increased risk of rejection, biliary stricture formation, or disease recurrence in the transplanted liver[21] Initial studies of vancomycin therapy have shown normalization of liver function test results in patients with primary sclerosing cholangitis, but longterm results are not yet available.[21,22]

Primary biliary cirrhosis mostly occurs in middle-aged women but has been identified in adolescents. This disease is characterized by the presence of antimitochondrial antibodies.[23]

Metabolic Disorders

Metabolic disorders are uncommon causes of chronic hepatitis but should be considered, especially when initial testing for infectious causes does not yield a diagnosis.[2,3] The clinical presentation of these disorders usually is not distinctive enough to permit diagnosis without laboratory testing, including liver biopsy.

Although α_1-antitrypsin deficiency most commonly affects the lungs, it can cause chronic liver disease in all age groups, including neonates, who usually present with cholestatic jaundice.[24,25] Liver involvement in some infants progresses to cirrhosis and early death, but many patients do not develop signs of chronic liver failure until late adolescence.[24,25] Liver disease developing later in childhood or in adolescence can be associated with a wide spectrum of histologic findings ranging from mild portal fibrosis to cirrhosis or hepatoma. The diagnosis is established by measuring the serum α_1-antitrypsin level and protease inhibitor type of the affected person.[24,25] Severe disease occurs most often in people with homozygous protease inhibitor type ZZ but can occur in heterozygotes having MZ, SZ, and Z null phenotypes.[24,25] Although the current treatment for severe liver disease from α_1-antitrypsin deficiency is liver transplantation, various newer therapies to stimulate the production of α_1-antitrypsin are being studied. These trials include the use of carbamazepine, fluphenazine, and pimozide.[24] Hepatocyte transplantation and gene therapy are other strategies being studied.[24]

Chronic hepatic dysfunction occurs in up to 50% of children with cystic fibrosis and can include steatosis, cholelithiasis, focal biliary cirrhosis, and portal hypertension.[26,27] Except in the first year of life, liver disease rarely is the initial manifestation of cystic fibrosis, so diagnostic difficulties usually are not encountered. The diagnosis of cystic fibrosis can be made by newborn screening, sweat testing, or genetic screening for the most common mutations.[26,27]

Disorders of carbohydrate (e.g., glycogen storage disease), protein (e.g., chronic form of tyrosinemia), and lipid (e.g., Niemann-Pick and Gaucher disease) metabolism rarely manifest after the neonatal period as chronic hepatitis.[2] These diseases often require liver biopsy, as well as laboratory evaluation for diagnosis. They usually are not included in the initial evaluation unless the patient has signs and symptoms such as hypoglycemia, seizures, or developmental delay.

Wilson disease can manifest as acute, chronic, or fulminant hepatitis, and because it is potentially treatable, it must be part of the differential diagnosis of chronic hepatitis in children and adolescents.[28,29] Wilson disease rarely is reported in children <3 years of age but should be considered in older children when liver disease is associated with hemolytic anemia, renal disease, or neuropsychological deterioration.[28] Kayser-Fleischer ring, a brownish-yellow ring around the corneoscleral junction, is the most distinctive finding on physical examination but may not be present in younger children or children with liver involvement alone.[28,29] The diagnosis is suggested by low serum ceruloplasmin levels and elevated urinary copper levels (especially after penicillamine treatment) and is confirmed by elevated levels of copper in the liver biopsy specimen.[28,29] A Wilson disease gene has been identified, and mutation analysis by gene sequencing for *ATP7*B can be a valuable tool in the diagnosis of cases that are indeterminate or difficult to diagnose.[28,29] Treatment requires the lifelong use of chelating agents such as D-penicillamine, trientine, or zinc.[29] Patients also need to be maintained on a low-copper diet. The use of tetrathiomolybdate is being evaluated as a potential therapy.[28] Liver transplantation is often required for patients with decompensated disease or acute liver failure.

Liver disease, although seldom severe, has been observed in association with celiac disease. The diagnosis should be considered in all patients with hepatitis when no other cause can be found.[30]

Toxins and Drugs

Patients with chronic hepatitis should be questioned for a history of exposures to toxins or drugs, including α-methyldopa, nitrofurantoin, isoniazid, dantrolene, propylthiouracil, valproic acid, and sulfonamide.[31,32] Affected people often have markers of autoimmune diseases, including positive lupus erythematosus slide preparation test results and elevated antinuclear antibodies.[32] Discontinuation of the drug usually results in improvement or resolution of the clinical and biochemical abnormalities. The timing of toxic drug reactions is unpredictable, and these reactions can occur after years of regular use of a medication. Longterm total parenteral nutrition also can be an important cause of chronic hepatitis in children, particularly in children with short bowel syndrome.[33]

Idiopathic and Anatomic Causes

Cryptogenic hepatitis (hepatitis of unknown cause) is a diagnosis of exclusion when all the previously described causes have been excluded. Depending on the location and age of the population studied, cryptogenic hepatitis accounts for approximately 25% of cases of chronic hepatitis.[2,3] Analysis of risk factors in adults suggests that silently progressive fatty liver may be an underrecognized cause of cryptogenic cirrhosis.[34]

Neonatal hepatitis, which comprises a group of disorders of unknown origin that cause cholestasis in neonates, also is a diagnosis of exclusion. This diagnosis usually is made early in the neonatal period; patients rarely go unrecognized until later infancy. The number of cases of neonatal hepatitis is decreasing as more sophisticated methods of diagnosis identify new diseases, especially errors in bile salt metabolism and progressive familial intrahepatic cholestasis.[35,36]

Granulomatous Hepatitis

Beverly L. Connelly

Histologically evident granulomas in the liver are referred to as *granulomatous hepatitis*. Granulomas can be an incidental finding, as in biopsies performed in prospective organ donors[1] or can be a manifestation of a disorder primarily of the liver, but they more often are a part of an underlying systemic process.[2] Levels of serum hepatic enzymes are normal or only minimally elevated.[2]

Granulomas are reported in 2% to 15% of liver biopsy specimens from adults and 4% to 7% of specimens from children.[3,4] Increased use of computed tomography (CT) and magnetic resonance imaging (MRI) for patient evaluations has led to increasing recognition of granulomatous hepatitis and spurred the search for causes.

Pathogenesis and Pathologic Findings

The hallmark of hepatic granulomas is epithelioid cells, which are activated macrophages transformed to resemble epithelial cells. Granuloma formation is initiated when monocytes and macrophages migrate into an area of inflammation in response to triggering by intracellular microbial antigens, foreign body reactions, and host immunologic hypersensitivity responses.[5] A Th1 or Th2 pathway can be active in granuloma formation. The Th1 immune response is classically involved in tuberculosis and sarcoidosis, and the Th2 response occurs with parasitic infections. T-lymphocyte–derived tumor necrosis factor (TNF) plays a key role in granuloma formation, a finding supported by the enhanced risk of granulomatous infections by patients receiving TNF-inhibitor agents.[6,7]

Hepatic granulomas are 50 to 300 mm in diameter, and their morphology varies from clusters of epithelioid cells to well-developed granulomas rimmed by lymphocytes.[5,8] Epithelioid cells can merge to form multinucleated giant cells. Central caseation or abscess formation can occur. Distribution of epithelioid cells often is patchy, and the small granulomas may be identified only with serial tissue section analysis.[2,5]

Histologic features can suggest specific diagnoses.[5] Central caseation with epithelioid cells in a radial array at the periphery is typical of tuberculosis, and Langhans giant cells can be seen. Granulomas are large and loose in sarcoidosis, without pattern or caseation, although there can be central eosinophilic necrosis and multinucleated giant cells.[5,9] In chronic granulomatous disease of childhood, pigmented macrophages are found in architecturally normal liver, and necrotizing granulomas are found in areas of active inflammation.[5,10] *Bartonella henselae* causes granulomas with stellate microabscess.[5,11] Eosinophilic infiltrates help to distinguish hepatic granulomas caused by parasitic infestations, and a portion of the larva may seen within the granulomas of visceral larva migrans or the ova in schistosomiasis.[5,12] Eosinophilic granules also can be seen with histoplasmosis.

Special histologic stains and techniques should be used when an infectious cause is suspected. Acid-fast bacilli (AFB) are demonstrated infrequently in granulomas caused by *Mycobacterium tuberculosis*, whereas large numbers of AFB usually are found in patients with the acquired immunodeficiency syndrome (AIDS) who are infected with nontuberculous mycobacteria.[13] Immunohistochemistry techniques can aid in identifying viruses, especially cytomegalovirus (CMV) and Epstein-Barr virus (EBV). Nucleic acid amplification techniques can be useful for identifying various pathogens in tissues.[14]

Clinical Manifestations and Differential Diagnosis

Hepatic granulomas usually reflect a systemic disease.[8] When granulomas are limited to the liver, primary biliary cirrhosis is an important diagnosis for adults.[3]

Clinical manifestations vary with the underlying disease. Fever and chills often are primary symptoms and may be a manifestation in fever of unknown origin.[15] Mild right upper quadrant abdominal pain and tenderness may be found, but serum hepatic enzyme levels usually are normal or mildly elevated.

Although noninfectious causes are more common in adults in case series from western countries,[14,16] infectious causes predominate in children[4,17] and in series from the Middle East and India.[4,18] The principal infectious and noninfectious causes of granulomatous hepatitis are listed in Table 62.1.

TABLE 62.1

Agents and Conditions Associated With Granulomatous Hepatitis

Infectious Agents	Noninfectious Agents or Conditions
BACTERIA	**IMMUNE DYSREGULATION**
Bartonella henselae	Autoimmune hepatitis
Brucella spp.	Biliary cirrhosis, primary
Coxiella burnetii	Chronic granulomatous disease
Francisella tularensis	Common variable immunodeficiency
Listeria monocytogenes	Inflammatory bowel disease
Mycobacterium tuberculosis	Juvenile idiopathic arthritis
Nontuberculous mycobacteria	Sarcoidosis
Nocardia spp.	Systemic lupus erythematosus
Pasteurella multocida	Wegener granulomatosis
Treponema pallidum	**DRUGS AND CHEMICALS**
Yersinia enterocolitica	Allopurinol
VIRUSES	Barium
Hepatitis C virus	Carbamazepine
Epstein-Barr virus	Mebendazole
Cytomegalovirus	Methyldopa
FUNGI	Antimicrobial agents: norfloxacin, penicillin
Blastomyces dermatitidis	Chemotherapeutic agents
Candida spp.	Phenytoin
Coccidioides immitis	Pyrazinamides
Cryptococcus neoformans	Sulfasalazine
Histoplasma capsulatum	Talc
PARASITES AND PROTOZOA	Quinine
Leishmania spp.	**NEOPLASMS**
Schistosoma spp.	Hodgkin disease
Strongyloides spp.	Lymphoma
Toxocara spp.	**IDIOPATHIC CONDITIONS**

Toxoplasma gondii	

Infectious Causes

The prevalence of causative infectious agents of granulomatous hepatitis reflects geography, socioeconomic factors, and host immunocompetence. Worldwide, mycobacteria are the most frequent bacterial cause of granulomatous hepatitis.[8,18] In case series from the Iran and India, more than one half of the cases were tuberculosis, typically as a part of systemic disease.[4,18] In one review of 63 patients with granulomatous hepatitis, 9 of 11 patients younger than 20 years had tuberculosis.[15] Nontuberculous mycobacteria are offenders in immunocompromised patients and those with AIDS and are part of disseminated infection.[13] Bacille Calmette-Guérin (BCG) can disseminate and cause granulomatous hepatitis in children with severe combined immunodeficiency and in adults who receive BCG instillation into the bladder as therapy for bladder carcinoma.[19,20]

Bartonella henselae infection is likely an underdiagnosed cause of granulomatous hepatitis in healthy and immunosuppressed children, who come to medical attention with abdominal pain and prolonged, undiagnosed fever.[11,21] Granulomatous hepatitis should be suspected in patients with atypical *B. henselae* infections.

With improved diagnostics, hepatitis C virus has emerged as a significant cause of granulomatous hepatitis, surpassing tuberculosis in western societies.[22,23] Chronic infection with other viral causes of hepatitis occasionally have been implicated in granuloma formation.[14]

Zoonotic infections, including brucellosis and Q fever (i.e., *Coxiella burnetii* infection), should be suspected in persons with liver lesions and exposure to sheep, goats, or other herded ungulates.[24] Isolated liver disease is unusual, however. Several tickborne infections, including ehrlichiosis, tularemia, and Lyme disease, rarely have been associated with granulomatous hepatitis.[25]

Among conditions caused by parasites and protozoa, schistosomiasis is a leading cause of hepatobiliary disease where the pathogens are prevalent in tropical and subtropical regions of Asia, the Caribbean, South America, and Africa.[5,26] Migrating larvae of *Toxocara canis* can lead to hepatic or splenic granulomatous disease associated with visceral larva migrans.[27] Peripheral eosinophilia often is significant, and organ enlargement can be severe in patients with parasitic granulomatous hepatitis.

Histoplasmosis is the most commonly reported fungal infection associated with granulomatous hepatitis in immunocompetent and immunocompromised patients.[4,17,28] Infections with other endemic dimorphic fungi also can involve the liver. Hepatic and splenic granulomas and abscesses due to *Candida* species are well-recognized complications in neutropenic and otherwise immunocompromised populations. Cryptococcal infections usually seen in immune compromising conditions, including AIDS, can be associated with granulomatous hepatitis.[28]

Noninfectious Causes

Autoimmune and immune dysregulation disorders account for most noninfectious granulomatous hepatitis cases.[5,8,14] Primary biliary cirrhosis is the most common cause of noninfectious granulomas isolated to the liver alone,[3,23] and sarcoidosis is the most common cause of hepatic granulomas seen as a part of a multisystem disease.[29] Hepatic granulomas can be part of the clinical manifestations of other conditions of immune dysregulation, such as chronic granulomatous disease,[30] common variable immunodeficiency, inflammatory bowel disease (e.g., Crohn disease), juvenile idiopathic arthritis,[5,8] and a variety of lymphoreticular disorders (e.g., Hodgkin disease).[31] In each of these conditions, it is important to exclude infectious causes.

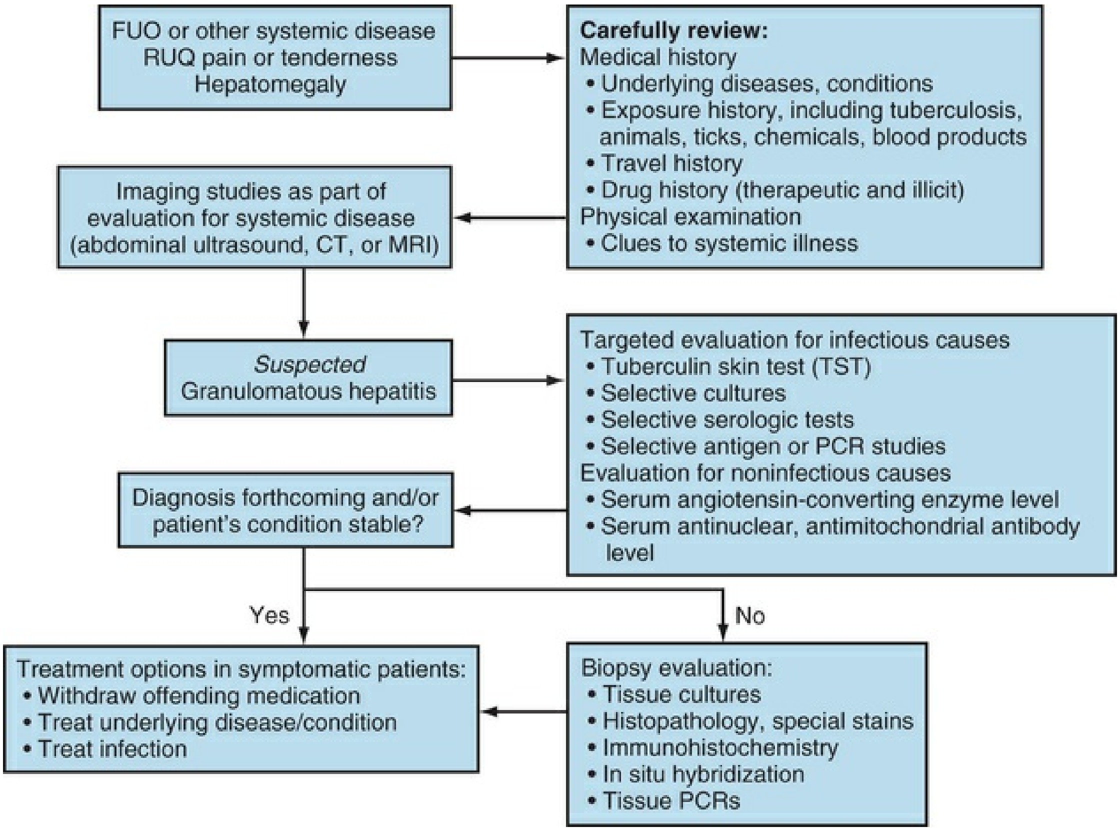
Drugs, toxins, inert materials, and chemicals can lead to noncaseating granulomatous inflammation of the liver. Chemotherapeutic agents, biologic agents, antibiotics, anticonvulsants, and anti-inflammatory agents are most frequently associated.[32–34] Many of the idiopathic cases of granulomatous hepatitis may be drug related.[33]

Diagnosis

Granulomatous hepatitis should be suspected in any patient with fever of unknown origin or with a systemic disorder in which right upper quadrant abdominal pain or tenderness, hepatomegaly, or a mild elevation of serum hepatic enzymes is seen. Liver lesions may be visualized on imaging studies as part of the evaluation of symptoms.

CT, MRI, and, less often, ultrasonography provide sensitive screening diagnostic modalities for granulomatous hepatitis. MRI can differentiate caseating from noncaseating granulomas.[35] The role of fluorodeoxyglucose position-emission tomography (FDG-PET) with CT in detection of liver granulomas is growing but requires clinical development.[36]

As depicted in Fig. 62.1, testing guided by a careful history to capture epidemiologic clues and attention on physical examination to clues for underlying systemic disease often can lead to the diagnosis and guide treatment without having to perform a liver biopsy. Because of the prevalence of viral infections such as EBV, CMV, and hepatitis C, testing for these pathogens in the absence of tissue examination may not be adequately specific.



FUO or other systemic disease
RUQ pain or tenderness
Hepatomegaly
Carefully review:
Medical history
• Underlying diseases, conditions
• Exposure history, including tuberculosis, animals, ticks, chemicals, blood products
• Travel history
• Drug history (therapeutic and illicit)
Physical examination
• Clues to systemic illness
Imaging studies as part of evaluation for systemic disease (abdominal ultrasound, CT, or MRI)
Suspected
Granulomatous hepatitis
Targeted evaluation for infectious causes
• Tuberculin skin test (TST)
• Selective cultures
• Selective serologic tests
• Selective antigen or PCR studies
Evaluation for noninfectious causes
• Serum angiotensin-converting enzyme level
• Serum antinuclear, antimitochondrial antibody level
Diagnosis forthcoming and/or patient's condition stable?
Yes
No
Treatment options in symptomatic patients:
• Withdraw offending medication
• Treat underlying disease/condition
• Treat infection
Biopsy evaluation:
• Tissue cultures
• Histopathology, special stains
• Immunohistochemistry
• In situ hybridization
• Tissue PCRs

FIGURE 62.1 An approach to the diagnosis of granulomatous hepatitis. CT, computed tomography; FUO, fever of unknown origin; MRI, magnetic resonance imaging; PCR, polymerase chain reaction;

RUQ, right upper quadrant.

In immunocompromised people and those with progressive symptoms without a compelling diagnosis, a tissue diagnosis should be sought. Tissue from a lymph node or skin lesion in a patient with systemic disease may provide the diagnosis, avoiding the more invasive liver biopsy. Tissue cultures may yield the pathogen. Histopathologic clues from routine and special stains can guide immunohistochemistry (i.e., in situ hybridization) and nucleic acid amplification testing (i.e., PCR) of tissue specimens and substantially increase detection of most infectious agents.[14] Further serologic studies and serum PCR studies then may be indicated. Thorough investigation for all possible causative diseases should be performed before the condition is labeled idiopathic.

Management and Outcome

Granulomatous hepatitis of infectious origin regresses with appropriate targeted therapy. Treatment of the underlying disease, however, is the cornerstone of management. Empiric therapy with corticosteroids has been advocated in idiopathic adult cases, although illness can resolve without therapy in these patients.[37]

There are no collective data regarding the outcome of children with idiopathic granulomatous hepatitis. Empiric therapy with corticosteroids is rarely indicated in children in view of the predominance of infectious causes of pediatric cases.

Acute Pancreatitis

Beverly L. Connelly

Although it is a rare disorder in children, pediatric hospital admissions for pancreatitis have increased over the past decade.[1–3] A possible reason for the rising incidence is an increased awareness by pediatricians of pancreatitis as a cause of abdominal pain in children.[3] In its mild form, pediatric pancreatitis likely is underdiagnosed, and it resolves spontaneously with no sequelae.

Etiologic factors leading to pancreatitis include a wide variety of disorders that vary in incidence by age. Among adults, alcohol and gallstones are the major causes of acute pancreatitis,[2] whereas in children, the causes are more diverse. In children, pancreatitis most often results from systemic illness, biliary disease, trauma, or the side effects of certain medications.[2–7] Infection or infestation accounts for about 10% of cases of acute pancreatitis in children.[3,8]

Pathogenesis

Inflammation of the pancreas in response to a variety of insults is caused by autodigestion of the organ by pancreatic enzymes. The precise circumstances and chronology of events leading to enzyme activation vary by cause.[2,9] The end result is that enzymes are activated within the pancreatic parenchyma, producing local inflammation and damage.

The inflammatory cascade that follows pancreatic injury results in the systemic inflammatory response syndrome (SIRS). Interleukin-1 (IL-1) and tumor necrosis factor (TNF) mediate this response. These agents increase production of platelet-activating factor (PAF), nitric oxide, IL-6, and IL-8. Inflammatory mediators are responsible for the clinical findings of severe acute pancreatitis such as acute respiratory distress syndrome (ARDS), vascular leakage, renal dysfunction, hypovolemia, and shock. Other factors such as activated complement (C5) and IL-10 may act to dampen the inflammatory response.[9,10]

Clinical Manifestations

Abdominal pain is the predominant symptom, occurring in 87% of pediatric patients.[8] Continuous, dull pain typically occurs in the epigastric area. Pain begins abruptly, increases in severity, and peaks in a few hours. Sometimes the pain is mild, is localized elsewhere in the abdomen, or radiates to the middle of the back.[4] Nausea and vomiting occur in 64% of pediatric patients.[8] The child's position of comfort usually is with the knees flexed on the abdomen.

Compared with older children with pancreatitis, infants and toddlers can have significantly fewer signs and symptoms of abdominal pain, epigastric tenderness, or nausea.[11] Epigastric or midabdominal tenderness with guarding often is found on physical examination. Bowel sounds disappear as ileus develops. An abdominal mass can develop as a manifestation of a pancreatic pseudocyst. Rigid abdomen and periumbilical discoloration suggesting intra-abdominal hemorrhage are rare and represent signs of severe pancreatitis.[4,11] In pediatrics, most cases of pancreatitis are mild and have a spontaneous resolution.

Diagnosis

The diagnosis of acute pancreatitis relies on clinical symptoms and should be considered for any child manifesting upper or diffuse abdominal pain or shock.[4,8] No single definitive diagnostic test is available. A comprehensive history highlighting potential causes should be elicited.

The diagnosis usually is confirmed by the finding of elevated serum pancreatic enzymes. An elevated total serum amylase level has a sensitivity of 95% to 100% if tested within the first 24 hours after onset of symptoms. The serum amylase level tends to fall within 48 hours of onset. However, specificity and positive predictive value of an elevated serum amylase level are low.[12] Serum lipase is more specific for pancreatic inflammation and is more sensitive in later stages of the disease.[4,12] When used together, elevated serum amylase and serum lipase values yield a specificity of 90% to 95%.[13] Persistence of elevated amylase levels beyond 48 hours after the onset of symptoms raises the possibility of a pancreatic pseudocyst.

Abdominal ultrasonography is the best initial imaging study when pancreatitis is suspected. Ultrasonography can show swelling of the pancreas, but most importantly, it helps to exclude surgically treatable causes of pancreatitis such as gallstones and extrapancreatic masses. A plain film of the abdomen is useful to exclude other causes of abdominal pain. Pancreatic calcification can occur in patients with acute recurrent or chronic pancreatitis.

Intravenous contrast-enhanced abdominal computed tomography is the most useful modality for the diagnosis of significant abdominal trauma, necrotizing pancreatitis, and pseudocyst,[14] and it should be performed in all cases of severe pancreatitis to guide therapy. Endoscopic retrograde cholangiopancreatography (ERCP) or magnetic resonance cholangiopancreatography (MRCP) can be useful in selected cases, particularly when therapeutic intervention is needed.

Differential Diagnosis

The differential diagnosis of acute pancreatitis varies with the severity of the pancreatitis attack. In its mild forms (i.e., most common presentation in children), pancreatitis can mimic acute gastroenteritis. Vomiting often is the principal symptom of very young children.[11] Mild acute pancreatitis also can occur during acute viral gastroenteritis. Biliary tract disease (e.g., cholelithiasis, choledocholithiasis, choledochal cyst), peptic ulcer disease (i.e., penetrating or perforated peptic ulcer), intestinal obstruction, and factitious pancreatitis should be excluded. Renal failure and diabetic ketoacidosis can be responsible for falsely elevated serum amylase levels and should be excluded.

Infectious Causes

Infectious agents are responsible for a few cases of acute pancreatitis. Although many infectious agents have been implicated (Box 63.1), evidence supporting their causality usually is indirect and based on results of serologic assays or epidemiologic association. It is likely that undiagnosed but self-limited viral illnesses account for many idiopathic cases of acute pancreatitis.

Box 63.1

Common Infectious Causes of Acute Pancreatitis in Children

Viruses

Mumps virus

Coxsackie B viruses

Hepatitis viruses: A, B, C, and E

Herpesviruses: cytomegalovirus (CMV), Epstein-Barr virus (EBV), herpes simplex virus (HSV), varicella-zoster virus (VZV)

Human immunodeficiency virus (HIV)

Influenza A virus

Rotavirus

Parasites

Ascaris lumbricoides

Clonorchis sinensis

Cryptosporidium parvum

Echinococcus granulosus

Bacteria

Mycoplasma pneumoniae

Salmonella spp.

Leptospira spp.

The most recognized viral cause of pancreatitis is the mumps virus.[5] Mild pancreatitis occurs in up to 15% of patients with mumps. Parotitis usually precedes abdominal pain and vomiting by 4 to 5 days; pancreatitis rarely occurs alone. Enteroviruses, especially group B coxsackieviruses, also are implicated and have been studied in the context of diabetes.[15,16] Human herpesvirus infections, including cytomegalovirus, Epstein-Barr virus (EBV), herpes simplex virus, and varicella-zoster virus, have been rarely reported to induce pancreatitis.[17–19]

Hepatitis B viral antigens have been demonstrated in the acinar cells of the pancreas and are associated with inflammation.[20] Acute pancreatitis associated with nonfulminant hepatitis A and E is being recognized more frequently and is more common in boys and young men during the second and third weeks of illness. Hepatitis E appears to be associated with more severe pancreatitis.[21]

Pancreatitis in patients with human immunodeficiency virus (HIV) infection can be a direct effect of the disease,[22] but it often results from an opportunistic copathogen or to antiretroviral therapy.[23,24] Pancreatitis unrelated to antiretroviral therapy is an indicator of poor prognosis in HIV-infected children.

Ascaris lumbricoides, *Clonorchis sinensis*, and *Cryptosporidium parvum* cause pancreatitis by physical obstruction of the pancreatic duct by migration from the intestinal lumen into the biliary or pancreatic ducts, or both.[25,26] Bacteria are unusual causes of acute pancreatitis, but enteric organisms complicate necrotizing pancreatitis and worsen the prognosis. Fungal pathogens have not been reported as causes of pancreatitis, but they can infect a necrotic pancreas.

Noninfectious Causes

The leading noninfectious causes of pancreatitis in all ages are shown in Box 63.2. Traumatic pancreatitis associated with blunt abdominal trauma from motor vehicle accidents, sports injuries, or nonaccidental trauma account for up to 40% of pediatric cases.[2]

Systemic inflammatory disorders such as Kawasaki disease, juvenile idiopathic arthritis, systemic lupus erythematosus, inflammatory bowel disease, and hemolytic uremic syndrome account for one third of cases.[2,3]

Box 63.2

Common Noninfectious Causes of Acute Pancreatitis in Children

Trauma

Motor vehicle accidents

Sports injuries

Child abuse

Anatomic Obstructions

Congenital duct anomalies

Annular pancreas

Tumor (blocking pancreatic duct)

Drugs

Corticosteroids

Valproic acid

Chemotherapeutics: L-asparaginase, 6-mercaptopurine, cyclophosphamide

Diuretics: thiazides, furosemide

Antiretrovirals: dideoxyinosine

Azathioprine

Inflammatory Diseases

Kawasaki syndrome

Juvenile idiopathic arthritis

Inflammatory bowel disease

Systemic lupus erythematosus

Henoch-Schönlein purpura

Stevens-Johnson syndrome

Major burns

Hereditary and Metabolic Disorders

Gene mutations: *PRSS1*, *SPINK1*, *CFTR* (cystic fibrosis)

Hyperlipidemia (types I, IV, and V)

Type 1 diabetes

Glycogen storage disease

Mitochondrial disorders

IDIOPATHIC CAUSES

Prescription medications and accidental ingestion of the drugs listed in Box 63.2 can be causal.[3,5,24,26–28] Valproic acid, L-asparaginase, 6-mercaptopurine, and prednisone are the leading drug causes of pancreatitis in children.[3,5] Corticosteroids may be the most commonly implicated drugs causing pancreatitis in children. Pancreatitis after bone marrow transplantation can occur during graft-versus-host disease,[29] possibly as a consequence of corticosteroid treatment. For many other conditions, it is unclear whether corticosteroid therapy or the underlying inflammatory condition is causative.

In infants and toddlers, acute pancreatitis most often is associated with multisystem infection or disease, especially hemolytic uremic syndrome.[6] Acute pancreatitis after liver transplantation likely is caused by a combination of trauma, inflammation, and drugs.[30]

Hereditary pancreatitis, which manifests first in infancy or adolescence, is increasingly recognized.[31] Individuals with mutations in the protease serine 1 *(PRSS1)* gene (which encodes cationic trypsinogen),[32,33] the serine peptidase inhibitor Kazal type 1 *(SPINK1)* gene (which encodes a trypsin inhibitor),[32,34,35] or the cystic fibrosis transmembrane conductance regulator *(CFTR)* gene (which encodes the CFTR protein)[32,36] are at increased risk for acute or chronic pancreatitis.

Treatment

Therapy for acute pancreatitis primarily is supportive and is dictated by the severity of the multiorgan dysfunction that can complicate pancreatitis. Withdrawing an offending agent or treatment of an underlying systemic inflammatory disorder is a critical component of care. Nasogastric suction is used only for symptomatic relief in patients with ileus or severe vomiting. Early aggressive fluid resuscitation has been associated with a reduction in the inflammatory response syndrome and multiple organ failure.

Early enteral feeding (within 24–72 hours) is superior to the traditional approach of bowel rest. Enteral nutrition is thought to maintain the integrity of the intestinal mucosa, reducing the potential for translocation of enteric flora.[2] Bowel rest is indicated only if pain continues or a complication arises.

Meperidine hydrochloride is usually selected for pain control because it has a less constrictive effect on the sphincter of Oddi than does morphine. The administration of broad-spectrum antibiotics to patients with severe, necrotizing pancreatitis (rare in pediatric cases) results in improved mortality and morbidity rates.[37]

Clinical Course

Most children recover completely from acute pancreatitis. Mortality rates for children are not defined clearly but most often reflect the severity of the underlying cause. Death or complications are more likely in those with pancreatic or peripancreatic hemorrhage or necrosis, which presages a complicated acute course that can include hemodynamic instability, serious biochemical abnormalities, and multiorgan failure. Local complications include the formation of an abscess or pseudocyst. Development of a secondary fever indicates a possible complication; abdominal ultrasonography or computed tomography is indicated. Surgical consultation should be sought for complicated cases.

Cholecystitis and Cholangitis

Beverly L. Connelly

Cholecystitis and cholangitis refer to inflammation of the gallbladder and extrahepatic bile ducts, respectively. Both occur much more commonly in adults than in children but are encountered often enough to be important to clinicians caring for children with acute abdominal illnesses.

Pathogenesis

Cholecystitis is inflammation of the gallbladder, and 90% to 95% of cases are attributed to obstruction of the neck of the gallbladder or the cystic duct by biliary stones (i.e., cholelithiasis).[1] Gallstones frequently are found in asymptomatic individuals; only an estimated 1% to 3% of people with gallstones develop acute cholecystitis.[2] Anatomic abnormalities, stricture of the bile duct after surgery, and stenosis associated with malignancy also can cause obstruction.

The degree and duration of obstruction influence the type of symptoms. If obstruction is partial and brief, symptoms of biliary colic can occur. If the obstruction is complete and prolonged, acute cholecystitis results. The increased intraluminal pressure in combination with bile supersaturated with cholesterol triggers an acute inflammatory response. Secondary bacterial infection can occur in 7 to 10 days if the obstruction is not relieved.[1] Although stones are the most common causes of obstruction, any anatomic or physiologic obstruction can begin the cycle.

Biliary stones are classified as pigment (bilirubin) stones or cholesterol stones. Pigment stones are black or brown. Black pigment stones are not thought to be associated with infection but are associated with hemoglobinopathies (e.g., spherocytosis, thalassemia, sickle cell anemia), advancing age, and cirrhosis.[2] Brown pigment stones are bacteria laden; bacterial β-glucuronidase deconjugates bile acids that then precipitate, forming a stone. Brown stones also can form with nonbacterial pathogens. Cholesterol stones are the most common type of stones and generally are thought not to be infectious in origin. Cholesterol stones form when bile is supersaturated with cholesterol excreted by the liver that forms a precipitate.[2]

Total parenteral nutrition and use of diuretics are predisposing conditions for the formation of biliary sludge and stones in children. Treatment with third-generation cephalosporins can result in biliary sludge (i.e., pseudolithiasis) in children, but it does not lead to cholecystitis.[3]

Acute cholangitis is a systemic process that results from obstruction of bile flow in combination with bacterial growth in the bile. Biliary infection alone is insufficient; progressive obstruction leads to increased intraductal pressure with cholangiovenous and cholangiolymphatic reflux. Bacteria translocate into the bloodstream, causing septicemia.[4]

The incidence of acute cholangitis as a consequence of sclerosing cholangitis and endoscopic manipulation of the biliary tract is increasing.[1] Portoenterostomy (i.e., Kasai procedure), the classic surgical procedure performed for biliary atresia, predisposes children to recurrent cholangitis. Use of the intestinal conduit to restore bile flow from the liver to the small intestine can allow the ascent of intestinal flora and cholangitis.[5,6] Most episodes of cholangitis after the Kasai procedure occur during the first 3 postoperative months; only a few children experience cholangitis after 1 year of age.[7] Because of this well-recognized risk, patients usually are given antibiotic prophylaxis with trimethoprim-sulfamethoxazole (TMP-SMX) for 6 to 12 months. Similarly, cholangitis occurs, although less frequently, in children who have undergone orthotopic liver transplantation using a Roux-en-Y procedure for a biliary conduit.

Other rare causes of impaired biliary drainage predisposing to cholangitis include choledochal cyst, Caroli disease, primary sclerosing cholangitis, biliary stricture after abdominal trauma, prior duct surgery, cystic fibrosis, and tumors of the extrahepatic ducts (e.g., rhabdomyosarcoma, neuroblastoma).[1] Immunoglobulin G subclass 4–related sclerosing cholangitis is associated with autoimmune pancreatitis and involvement of many other organs.[8]

In areas of high endemicity, biliary obstruction can result from parasites migrating into the biliary tract. Most commonly, the round worm *Ascaris lumbricoides* can migrate into the bile ducts as a part of an intestinal infestation. The larvae of the liver fluke *Clonorchis sinensis*, acquired from infested, undercooked freshwater fish, migrate from the duodenum to the common bile duct and upward, where they develop into adult flukes that can inhabit the biliary tract for several years.[9] Another liver fluke, *Fasciola hepatica,* which is acquired by ingesting cercarial-contaminated aquatic plants, gains access to the biliary tract by the peritoneum and, through the liver capsule. The metacercaria lodge in the biliary tract and develop into mature adult flukes.[9]

Ductal obstruction from any cause results in increased intraductal pressure or distention of the gallbladder, or both. Superinfection of the stagnant bile with organisms of gut flora follows, along with edema and congestion, further compromising the blood supply and lymphatic drainage. Tissue necrosis follows, favoring further bacterial proliferation. In cholangitis, the risk of bacteremia and septicemia is high, and mortality is 2.7% to 10%.[1]

Although obstruction to biliary drainage remains the most frequent cause for cholecystis, cholecystitis occasionally occurs without obstruction. This condition, known as acalculous cholecystitis, occurs in critically ill patients after trauma, burns, and major operations.[10] Acalculous cholecystitis also has been reported in children with infections caused by *Mycoplasma pneumoniae, Salmonella enterica* serovar Typhi and nontyphoidal species, *Shigella* species, and *Giardia lamblia*.[11] Acute acalculous distention (i.e., hydrops) of the gallbladder can occur acutely in infants and children and is associated with a variety of infections and inflammatory conditions (e.g., Kawasaki disease, streptococcal pharyngitis, septicemia, toxic shock syndromes, Henoch-Schönlein purpura), and during prolonged fasting and total parenteral nutrition. A markedly distended, thick-walled gallbladder without distention containing echo-free fluid can be seen by ultrasonography. The course usually is self-resolving.

Etiology

Normally, bile is sterile, but it can become colonized with intestinal bacteria that gain access from the duodenum through the sphincter of Oddi. In the absence of obstruction, colonization rarely progresses to cholangitis.[4]

Commonly isolated organisms from biliary tract infections include gram-negative enteric bacilli such as *Escherichia coli* (31% to 44% of cases), *Klebsiella* spp. (9% to 20%), *Pseudomonas* spp. (0.5% to 9%), and *Enterobacter* spp. (5% to 9%). Identified gram-positive organisms are *Enterococcus* spp. (3% to 34%) and *Streptococcus* spp. (2% to 10%). Anaerobes are *Bacteroides* spp. and *Clostridia* spp.) (4% to 20%).[12] Anaerobic infections are more common in patients who have had biliary tract surgery, biliary-intestinal anastomosis, or chronic biliary tract infections. *Candida* species predominantly are associated with intestinal disease (e.g., necrotizing enterocolitis), surgery, prolonged antibiotic therapy, total parenteral nutrition, proton pump inhibitor therapy, and immune suppression.

Positive blood cultures are reported for 21% to 70% of adults with acute cholangitis and approximately 50% of children.[13] Polymicrobial infections are common (26.9%), and in one third of cases, different organisms may be isolated from bile than are found in the bloodstream.[14] Discordance is particularly evident for anaerobes in bile that are uncommonly isolated from blood. Concordance usually is reported when liver and bile are sampled in patients with acute cholangitis.[13]

Clinical and Laboratory Features

The clinical triad of fever, right upper quadrant pain, and jaundice is a classic alert for biliary tract disease. Clinical manifestations of cholecystitis typically are milder than those of cholangitis, but there can be substantial overlap. Cholecystitis usually is heralded by mild epigastric pain with nausea and vomiting, followed by the pain shifting to the right upper quadrant, sometimes with radiation to the right shoulder or scapula. Pain usually is aggravated by movement or deep breathing. The gallbladder is palpable in less than 50% of cases.

Moderate temperature elevation and mild icterus can be evident, but high spiking fevers, chills, prominent jaundice, circulatory collapse, and other findings of gram-negative bacillary septicemia suggest cholangitis. There also can be signs of localized peritonitis, including guarding, rigidity, and rebound tenderness.[4]

The white blood cell count is normal or slightly elevated in cholecystitis and typically is substantially increased with a shift to immature forms with cholangitis. In patients with cholecystitis, serum levels of bilirubin and aspartate aminotransferase (AST) are elevated in about 50%, and the alkaline phosphatase level is elevated in about 25%. In contrast, most patients with cholangitis have elevated bilirubin, AST, and alkaline phosphatase levels. The degree of abnormality is greater in those with cholangitis than in those with cholecystitis. Serum amylase concentrations can be elevated in both disorders. Disseminated intravascular coagulopathy can occur with cholangitis.

Diagnosis

The differential diagnosis of acute cholecystitis and cholangitis includes appendicitis, pancreatitis, perforating ulcer, acute pyelonephritis, biliary colic without cholecystitis, hepatitis, perihepatitis (i.e., Fitz-Hugh–Curtis syndrome), and right lower lobe pneumonia. A definitive diagnosis is aided by imaging studies, the main goal of which is the detection of biliary obstruction and the likely cause.[4] Modalities commonly used include transabdominal ultrasonography (US), computed tomography (CT), magnetic resonance imaging (MRI), magnetic resonance cholangiopancreatography (MRCP), endoscopic ultrasound (EUS), endoscopic retrograde cholangiopancreatography (ERCP), and percutaneous transhepatic cholangiography (PTC), depending on availability, physician expertise, and preference.[4] Since the advent of these testing modalities, use of cholecystography has declined in the diagnostic evaluation of suspected cholecystitis or cholangitis.

For patients with mild symptoms, US is the usual noninvasive way to establish the diagnosis and guide further management. US is expected to demonstrate thickening and edema of the gallbladder wall and surrounding tissue in cholecystitis and dilation of bile ducts in cholangitis. US also can uncover the underlying cause of biliary tract disease by demonstrating stones, a choledochal cyst, or other obstruction to bile flow. MRCP is emerging as another nonradiation, noninvasive diagnostic modality for evaluating the biliary tract. PCT and ERCP are useful diagnostic tools that also can relieve obstruction and provide biliary drainage.[4]

A bile culture should be obtained at the time of any intervention. Positive cultures of bile specimens are reported for 59% to 93% of patients with acute cholangitis, and positive cultures of bile or gallbladder specimens are reported for 29% to 54% of patients with acute cholecystitis. Although no data confirm the value of routine blood cultures for patients with acute biliary disease, they are recommended for all severely ill patients.[12] Recovery of organisms from a liver biopsy provides the most definitive proof of cholangitis. However, a negative culture result for the liver specimen does not exclude the diagnosis of cholangitis in the seriously ill patient with confirmed bacteremia and other compelling features of the disease.

Management

The initial treatment of cholecystitis and cholangitis in children consists of supportive therapy and use of broad-spectrum antibiotic therapy effective against enteric gram-negative bacilli and anaerobic bacteria if there is a biliary-enteric anastomosis.[12] Drainage of the obstructed biliary tract is the mainstay of treatment for patients with cholangitis who are severely ill. Percutaneous or endoscopic drainage has replaced surgical intervention as the method of choice for emergent re-establishment of bile flow.[15]

Antibiotics are complementary to biliary drainage and should be initiated as soon as the diagnosis of biliary infection is suspected. Prompt antimicrobial treatment of the mildly or moderately ill patient may circumvent the need for an invasive procedure. Although guidelines for antimicrobial therapy in acute biliary infections have been published,[12,16] it is important to consider the local prevalence of extended-spectrum β-lactamase (ESBL)–producing *E. coli* and *Klebsiella* spp.

Ampicillin-sulbactam in combination with an aminoglycoside; cefazolin, cefuroxime, or ceftriaxone with or without metronidazole; and ciprofloxacin or levofloxacin with or without metronidazole are advocated regimens for less severe community-onset disease. An ampicillin- or piperacillin-containing regimen offers the advantage of enterococcal coverage. For more severe disease or in patients at risk for multidrug-resistant pathogens, treatment is provided by piperacillin-tazobactam or meropenem alone or by ceftriaxone, ceftazidime, or cefepime with or without metronidazole in combination with vancomycin for enterococcal coverage. These agents and combinations are expected to achieve excellent biliary levels of drug.

Coverage for anaerobic bacteria is essential in patients with biliary-enteric anastomoses. Therapy should be tailored further for isolated organisms and is continued for 7 to 10 days. Antibiotic prophylaxis with piperacillin, cefazolin, cefuroxime, ceftriaxone, or ciprofloxacin before therapeutic ERCP can reduce the risk of bacteremia and cholangitis.[17]

Medical management alone is expected to resolve the signs and symptoms in most cases of cholecystitis and cholangitis. Transition to oral agents (e.g., amoxicillin-clavulanate, cephalexin with or without metronidazole, ciprofloxacin or levofloxacin with or without metronidazole)[12] can be considered when the patient is afebrile, oral feeding is tolerated, and pain is adequately controlled.

Drainage is indicated for patients who fail to respond to medical management and in whom obstruction is demonstrated by ultrasound. Consultation with a gastroenterologist, interventional radiologist, or surgeon is recommended when drainage is indicated. Local expertise in endoscopic cholangiography to establish biliary drainage should be sought. Nonemergent laparoscopic cholecystectomy can be pursued after the active inflammatory process has subsided.[18] Cholecystectomy with exploration and drainage of the common bile duct or percutaneous transhepatic drainage now are performed infrequently.

Complications

Perforation occurs in up to 15% of cases of cholecystitis; sometimes peritonitis results, but more often, the perforation is spontaneously localized by surrounding omentum and serosa of contiguous viscera. When localized, perforation results in persistent fever, a palpable mass, and occasionally, a friction rub over the liver.

Pancreatitis and cholangitis can complicate cholecystitis. Cholangitis is a medical-surgical emergency and should be managed aggressively. Complications include perforation, macroscopic hepatic abscesses, pancreatitis, and septicemia.

Peritonitis

Shawn J. Rangel, Samuel E. Rice-Townsend, Mahima Karki, R. Lawrence Moss

Peritonitis is an inflammatory process involving the peritoneum, a specialized lining of the abdominal cavity that lubricates the abdominal organs and clears the cavity of infectious particles and other debris.

Infectious peritonitis classically has been described as primary or secondary, depending on the continuity of the gastrointestinal tract. Primary (i.e., spontaneous) bacterial peritonitis is an uncommon infection that develops in the setting of an intact gastrointestinal tract without an apparent source of inoculation. Secondary bacterial peritonitis is more common and arises from the inoculation with bacteria and other inflammatory debris after intestinal perforation or a postoperative anastomotic leak. Catheter-related infections comprise a third category, in which infections arise after contamination of the indwelling foreign body (e.g., peritoneal dialysis catheters, ventriculoperitoneal shunts).

Epidemiology

The overall incidence of infectious peritonitis among children is difficult to estimate due to the heterogeneity in diagnostic criteria and multiple underlying disease processes associated with the infection. Spontaneous bacterial peritonitis plus catheter-related peritonitis account for approximately 10% of cases of peritonitis in children.[1,2] The decreasing incidence of catheter-related peritonitis has resulted from improvements in catheter and connecting hardware technology used for continuous ambulatory peritoneal dialysis (CAPD) and the reduced frequency of touch contamination.[3–5]

The pediatric incidence of spontaneous bacterial peritonitis peaks between the ages of 5 and 9 years and affects boys and girls equally. Immunocompromised children are at greater risk for primary and catheter-related peritonitis compared with healthy children. Children with ascites due to portal hypertension are at particularly high risk for spontaneous peritonitis, with incidence rates exceeding 20% in some series.[6]

Spontaneous bacterial peritonitis has been associated with nephrotic syndrome. The reported incidence of peritonitis has been as high as 16% among children admitted with serious infectious complications attributable to nephrotic syndrome.[7] The first episode typically occurs during the first 2 years after diagnosis, and the overall incidence may be as high as 5%.[8–10] Risk factors for spontaneous bacterial peritonitis in patients with nephrotic syndrome include severe ascites, more advanced forms of the disease, and elevated serum cholesterol levels. Severe ascites, hypoalbuminemia, gastrointestinal bleeding, and recent endoscopic examinations have been identified as risk factors for children with cirrhosis.[7,11]

Catheter-related peritonitis remains a major concern for children receiving CAPD. Data from the US Renal Data System indicate that infectious complications remain the most frequent cause for hospitalization among children receiving CAPD, and up to two thirds of children receiving peritoneal dialysis experience at least one episode of peritonitis.[12] CAPD-associated peritonitis is especially common in children younger than 6 years of age, with the highest incidence reported for children younger than 1 year of age.[13] This high rate of infection may reflect the proximity of the catheter exit site to a gastrostomy tube and diaper or the frequent use of single-cuffed catheters in children and their shorter tunnel lengths.

The overall incidence of CAPD-associated peritonitis in the United States has decreased over the past several decades from one episode per 3 to 6 patient-months of dialysis to one episode per 14 to 24 patient-months.[13–15] Similar decreases in CAPD-associated peritonitis have been reported in Europe, and the lowest incidence of peritonitis has been observed among Japanese children.[16] These results have been attributed to an intensive CAPD training program and the rigorous attention to hygiene practiced in the Japanese culture.

Pathophysiology

Peritonitis can be caused by a variety of infectious and noninfectious insults that produce an inflammatory response involving the visceral and parietal peritoneum. The initial inflammatory response of the peritoneum to bacterial infection is characterized by vasodilation, tissue edema, transudation of fluid, and the influx of inflammatory macrophages and leukocytes. Lymphatic channels located in the undersurface of the diaphragm facilitate the clearance of bacteria, endotoxin, and other infectious particles from the peritoneal cavity. This drainage system provides an important adjunctive defense mechanism to the local cellular immune response. Impairment of this process by fibrin and inflammatory debris can result in accumulation of peritoneal fluid and dilution of immunoglobulins and opsonins. This may be particularly relevant to the pathophysiology of peritonitis in children with pre-existing ascites, in which serum and peritoneal concentrations of these immunoreactive molecules are lower than that seen in healthy children.[17]

Portal hypertension in patients with cirrhosis increases susceptibility to bacteremia and spontaneous peritonitis, likely due to the translocation of bacteria from the intestine and immune deficiencies related to neutropenia, impaired complement fixation, and decreased Kupffer cell function.[6,18] In patients undergoing CAPD, selective immunoglobulin (IgG) subgroup deficiencies may be an additional factor contributing to more severe peritonitis.[19]

Etiology

Primary Bacterial Peritonitis

Hematogenous seeding is the predominant source of primary bacterial peritonitis. Other sources of infection include lymphatic seeding, retrograde inoculation from a genitourinary source, and translocation of intestinal flora (Table 65.1). The bacteriologic profile of peritoneal infections largely depends on the mechanism of inoculation and underlying comorbidities (Table 65.2).

TABLE 65.1

Proposed Mechanisms and Associated Conditions for Peritonitis in Children

Primary Bacterial Peritonitis	Catheter-Associated Peritonitis	Secondary Bacterial Peritonitis
Hematogenous seeding (sepsis) Direct extension of localized process • Ascending urinary tract infection • Genital or pelvic infection • Mesenteric adenitis (TB) • Omphalitis Lymphogenous seeding Translocation of intestinal flora	Poor sterile technique during dialysis Migration of skin flora along catheter Direct extension of local infection • Exit-site infection (with CAPD) • CNS infection (with VP shunts) Hematogenous seeding of dialysate/CSF	Neonatal period • Necrotizing enterocolitis • Spontaneous gastric perforation • Feeding tube perforation (iatrogenic) • Intestinal volvulus • Hirschsprung disease Postneonatal period and childhood • Acute appendicitis • Intestinal volvulus • Intussusception • Incarcerated hernia

CAPD, continuous abdominal peritoneal dialysis; CNS, central nervous system; CSF, cerebrospinal fluid; TB, tuberculosis; VP, ventriculoperitoneal.

TABLE 65.2

Organisms Commonly Associated With Peritonitis in Children[a]

Primary Bacterial Peritonitis	Catheter-Associated Peritonitis	Secondary Bacterial Peritonitis
Previously healthy children • *Streptococcus pneumoniae* • Group A *Streptococcus* • *Staphylococcus aureus* • Gram-negative bacilli **Neonatal idiopathic primary peritonitis** • Group B *Streptococcus* • *Streptococcus pneumoniae* • *Staphylococcus aureus* • Enteric gram-negative bacilli **Nephrotic syndrome** • Coagulase-negative staphylococci • *Streptococcus* spp. • *Staphylococcus aureus* • Enteric gram-negative bacilli **Cirrhosis**	**CAPD associated** • Coagulase-negative staphylococci • *Staphylococcus aureus* • *Pseudomonas* spp. • Other enteric gram-negative bacilli • Fungi **VP shunt associated** • Coagulase-negative staphylococci • *Staphylococcus aureus* • *Escherichia coli* (late) • Other gram-negative bacilli (late)	**Proximal GI perforations** • Facultative organisms • *Escherichia coli* • *Klebsiella* spp. • *Enterobacter* spp. • *Pseudomonas* spp. • Gram-positive cocci **Anaerobic organisms** • *Bacteroides* spp. • *Clostridium* spp. • *Peptostreptococcus* spp. **Colonic perforations** • *Bacteroides fragilis* • Gram-negative bacilli (*Escherichia coli*) • Other anaerobic organisms • *Enterobacter* spp. (NEC)

• *Streptococcus pneumoniae*[b] • *Escherichia coli* • *Klebsiella* spp.	

[a] Organisms are listed in the order of relative incidence by category, although there may be substantial variation in microbiologic data over time and between different published series.

[b] The use of pneumococcal vaccines have decreased the rate of streptococcal peritonitis, although they are still more prevalent than gram-negative infections in most reported series.

CAPD, continuous abdominal peritoneal dialysis; GI, gastrointestinal; NEC, necrotizing enterocolitis; VPS, ventriculoperitoneal.

Primary peritoneal infections in healthy children often are monomicrobial, and *Streptococcus pneumoniae* is the most common cause.[7,2,21] In the past few decades, the rate of peritoneal infections caused by gram-negative organisms (especially *Escherichia coli*) has been increasing. This trend may reflect a decrease pneumococcal peritonitis related to universal use of pneumococcal conjugate vaccines.[20,22] Gram-positive organisms, particularly group B *Streptococcus,* predominate as the cause of primary peritoneal infections in neonates. These infections, also known as *neonatal idiopathic primary peritonitis*, are likely caused by hematogenous seeding in most cases, although infection also has been associated with omphalitis.[23] Group A *Streptococcus* can cause spontaneous peritonitis in otherwise healthy children.[24]

Mycobacterium tuberculosis is a rare cause of peritonitis but should be considered if the patient has been exposed to a known infected individual. Abdominal tuberculosis accounts for almost 12% of extrapulmonary disease and approximately 1% to 3% of all tuberculosis-associated infections.[25,26] The widespread practice of dairy pasteurization in the United States and other developed countries has effectively eliminated infection caused by *Mycobacterium bovis*.[27]

Peritoneal infection with *S. pneumoniae, Haemophilus influenzae, Neisseria gonorrhoeae,* and other encapsulated organisms should be considered in children with anatomic and functional asplenia. Gonococcal peritonitis can occur from ascending genital or pelvic infection. Infection can lead to inflammation of the liver capsule, resulting in gonococcal perihepatitis (i.e., Fitz-Hugh–Curtis syndrome).

Catheter-Associated Peritonitis

Cultures of peritoneal fluid are positive for approximately 75% of children with clinically apparent peritonitis occurring during peritoneal dialysis.[5] Between one half and two thirds of all episodes are caused by gram-positive organisms.[28,29] Coagulase-negative staphylococci (CoNS) and *Staphylococcus aureus* each account for about 15% of US cases.

The relative importance of gram-negative bacteria is increasing due to improved catheter connection technology, exit-site care, and antibiotic prophylaxis that reduces gram-positive bacterial contamination.[5,30] Gram-negative infections usually are associated with touch contamination and can be caused by a variety of organisms, including *Pseudomonas, Enterobacter, E. coli,* and *Klebsiella*.[28,31] In the United States, the most frequently isolated gram-negative organism is *Pseudomonas.*[32] *Pseudomonas* species are isolated from approximately 10% to 20% of catheter exit-site infections, suggesting a mechanism for bacterial migration along the catheter tunnel. Although gram-negative peritonitis in patients receiving CAPD can be caused by a secondary source (e.g., ruptured appendicitis), isolation of a single organism strongly suggests a catheter-associated cause.

Fungal peritonitis is a rare but serious complication of CAPD and is associated with substantial morbidity and mortality.[33–35] Although fungal pathogens account for only 3% to 6% of CAPD-associated pediatric cases, the incidence appears to be increasing.[34] Many patients with fungal peritonitis have had catheter-related infections treated with antibiotics, suggesting that these infections might be opportunistic. Compared with bacterial peritonitis, fungal peritonitis can be particularly difficult to treat, resulting in a greater likelihood of catheter loss and the need to convert to hemodialysis.[33,35] *Candida* species are the most commonly isolated fungus.[13]

Infectious peritonitis is a rare complication in children with indwelling ventriculoperitoneal shunts, affecting less than 1% of all patients.[36] Peritonitis can arise from contamination of intra-abdominal cerebrospinal fluid (CSF) by hematogenous seeding or bacterial translocation or from contamination of the peritoneal cavity by an infection originating in the central nervous system. In a patient with a ventriculoperitoneal shunt and abdominal pain, bacterial peritonitis must be differentiated from the more common CSF-containing pseudocyst. Ventriculoperitoneal shunt–associated peritoneal infections in the first several months after shunt placement usually are caused by gram-positive cocci (i.e., CoNS and *S. aureus*), whereas late infections are more likely to be caused by gram-negative organisms.[37,38] Secondary peritonitis after spontaneous erosion of the ventriculoperitoneal catheter into the colon has been reported.[39]

Secondary Bacterial Peritonitis

Secondary peritonitis can arise from any condition that results in the loss of gastrointestinal tract continuity (see Table 65.1). In the neonatal period, secondary peritonitis most often results from conditions that lead to intestinal ischemia and perforation, such as necrotizing enterocolitis, gastric perforation, meconium ileus, intestinal atresia, and Hirschsprung disease.[40–42] Acute appendicitis is the most common condition resulting in secondary peritonitis in older children. Intra-abdominal typhoid infections are common causes in poor and developing countries.[43]

In contrast to primary and catheter-related peritonitis, secondary infections tend to be polymicrobial, and the bacteriology depends most on the location of perforation. Aerobic and facultative gram-negative enteric organisms, including *E. coli, Klebsiella, Pseudomonas* spp., and *Candida* spp., are frequently isolated after perforation of the proximal gastrointestinal tract.[44] The colon contains predominately anaerobic and facultative organisms. *Bacteroides* species are the most commonly isolated organisms after colonic perforations.[44] In neonates with distal intestinal perforations, facultative enteric gram-negative bacilli are more commonly isolated than anaerobes, although *Bacteroides* and clostridia often are present.[45] In a large review of neonates with necrotizing enterocolitis, *Enterobacter* was the most common organism isolated, with anaerobes isolated in only 6% of cases.[45]

Clinical Presentation

The clinical presentation of patients with peritonitis depends on many factors, including age, underlying cause of infection, associated comorbidities, and immunologic status. The clinical presentation of the neonate frequently is nonspecific due to a paucity of localizing signs. The neonate usually appears ill, with marked abdominal distention, hypothermia, emesis, and respiratory distress.[46] The abdominal wall can appear erythematous or edematous if peritoneal inflammation is severe. Fever is not a common sign of peritonitis in the neonate.[46]

The clinical presentation of older children with peritonitis can include abdominal pain and tenderness, distention, vomiting, hypoactive bowel sounds, and various degrees of systemic toxicity. Neutropenic children and those receiving high doses of corticosteroids can have relatively benign presentations. These children often are afebrile and have minimal abdominal tenderness, leading to a misdiagnosis of gastroenteritis or another less serious ailment.

Fever or abdominal pain in any child undergoing CAPD should alert the clinician to the possibility of catheter-associated peritonitis, especially in the context of cloudy dialysis effluent. However, other noninfectious conditions, such as chemical peritonitis, eosinophilic peritonitis, hemoperitoneum, chylous ascites, and malignancy, also are associated with a cloudy appearance of the peritoneal effluent.[29] The clinical presentation of patients with ventriculoperitoneal shunt–associated peritonitis can be subtle, with the only symptoms being mild abdominal pain and low-grade fever. The specific organism causing infection can affect the clinical presentation and course. Gram-negative peritonitis often causes intense abdominal pain and is associated with dramatic alterations in the transport capacity of the peritoneal membrane.[13,47]

Peritonitis associated with tuberculosis often is insidious in onset and characterized by weight loss, chronic weakness, fever, night sweats, and anorexia.[26] Approximately 40% of patients with tuberculous peritonitis have symptoms and signs of active pulmonary infection.[26]

Diagnosis

Laboratory Evaluation

Laboratory findings in a child with peritonitis usually are nonspecific, often suggesting a systemic inflammatory process rather than a specific diagnosis. Blood cultures are positive for approximately 50% of children with nephrotic syndrome.[20] Elevated C-reactive protein (CRP) may be helpful in the early diagnosis of peritonitis in children with cirrhosis, but the diagnostic utility of CRP in patients with nephrotic syndrome and other underlying conditions is not known.[48]

Analysis of peritoneal fluid aspirates should be performed and can aid in differentiating primary from secondary peritonitis. Stool, amylase, or bile in aspirates indicates intestinal perforation, whereas blood can be associated with both primary and secondary peritonitis. For children undergoing CAPD, cloudy effluent with a white blood cell (WBC) count greater than 100 cells/mm^3 and a neutrophil predominance is adequate for the diagnosis of peritonitis and an indication to begin antibiotics empirically.[5]

Imaging

The primary utility of imaging in patients with suspected peritonitis is to help determine the cause (i.e., primary vs. secondary causes) and the necessity of urgent laparotomy. Although plain radiography and ultrasound may provide useful information (e.g., free air), computed tomography (CT) is the preferred test for evaluation of the child with an acute abdomen.

The finding of complex ascites, with or without visualization of the appendix, strongly suggests perforated appendicitis in older children. In the case of primary or catheter-related peritonitis, typical imaging findings include ascites, high-attenuation characteristics of peritoneal fluid, and nodular irregularity of the peritoneal lining.[49,50] CT findings for patients with abdominal tuberculosis can include thickening of the intestinal wall, lymphadenopathy, splenomegaly, ascites, and focal mesenteric calcifications.[51]

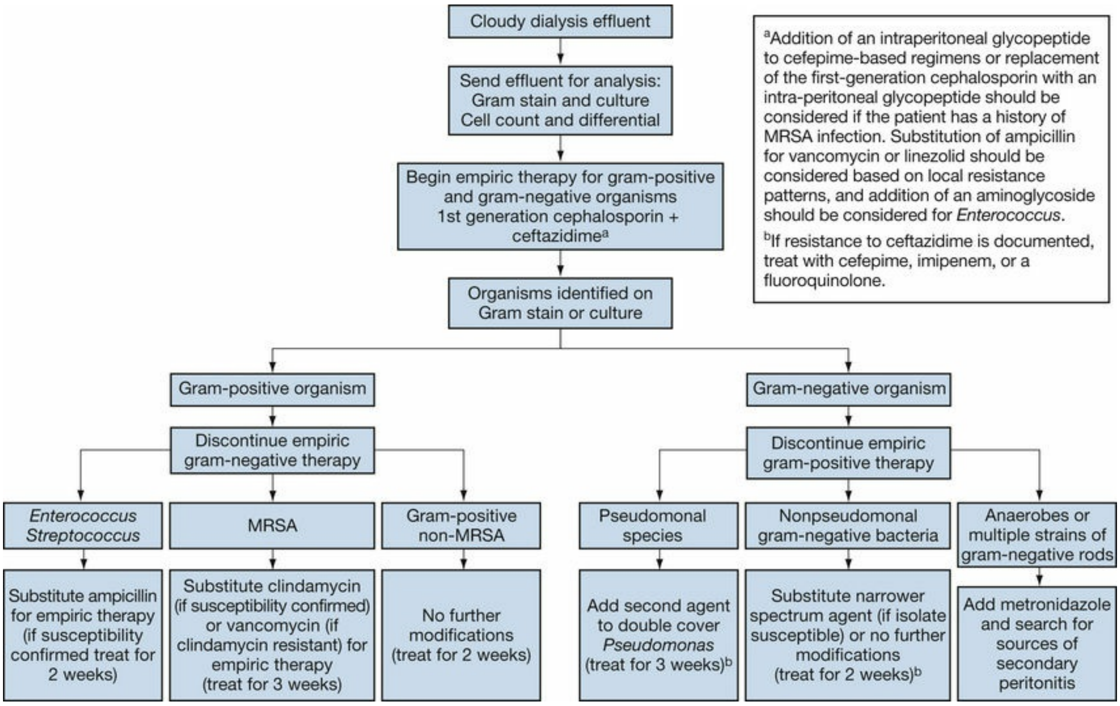
Management

Primary Peritonitis

In a child with an anatomically normal peritoneal cavity who develops primary bacterial peritonitis, antibiotic treatment should be directed at the most likely organisms, which include gram-positive cocci and gram-negative bacilli in children with nephrotic syndrome or cirrhosis and ascites (see Table 65.2).[20–22] Empiric therapy with cefotaxime or another third-generation cephalosporin is recommended.[11] Antibiotic therapy is tailored based on culture results from blood and peritoneal aspirates. Removal of infected peritoneal fluid has not been shown to improve outcomes and therefore is not recommended. Therapy generally is given for 14 days.

Catheter-Associated Peritonitis

Empiric antibiotics should be initiated when the diagnosis of bacterial peritonitis is suspected (Fig. 65.1). The wide variation in organisms associated with peritonitis in children treated with CAPD warrants the use of broad-spectrum agents until culture results are available. The combined intraperitoneal administration of a third-generation cephalosporin such as ceftazidime (or an aminoglycoside) and a first-generation cephalosporin is recommended as initial therapy. When available, intraperitoneal cefepime is acceptable as monotherapy (Table 65.3).[5,13,52] In a systematic review of antibiotic treatment, intermittent- or continuous-administration regimens were equivalent, but failures of intermittently administered ceftazidime for gram-negative bacillary peritonitis were relatively frequent.[12,53,54]



Cloudy dialysis effluent
Send effluent for analysis: Gram stain and culture Cell count and differential
Begin empiric therapy for gram-positive and gram-negative organisms 1st generation cephalosporin + ceftazidime[a]
Organisms identified on Gram stain or culture
Gram-positive organism
Discontinue empiric gram-negative therapy
Enterococcus Streptococcus
MRSA
Gram-positive non-MRSA
Substitute ampicillin for empiric therapy (if susceptibility confirmed treat for 2 weeks)
Substitute clindamycin (if susceptibility confirmed) or vancomycin (if clindamycin resistant) for empiric therapy (treat for 3 weeks)
No further modifications (treat for 2 weeks)
Gram-negative organism
Discontinue empiric gram-positive therapy
Pseudomonal species
Nonpseudomonal gram-negative bacteria
Anaerobes or multiple strains of gram-negative rods
Add second agent to double cover Pseudomonas (treat for 3 weeks)[b]
Substitute narrower spectrum agent (if isolate susceptible) or no further modifications (treat for 2 weeks)[b]
Add metronidazole and search for sources of secondary peritonitis
[a]Addition of an intraperitoneal glycopeptide to cefepime-based regimens or replacement of the first-generation cephalosporin with an intra-peritoneal glycopeptide should be considered if the patient has a history of MRSA infection. Substitution of ampicillin for vancomycin or linezolid should be considered based on local resistance patterns, and addition of an aminoglycoside should be considered for Enterococcus.
[b]If resistance to ceftazidime is documented, treat with cefepime, imipenem, or a fluoroquinolone.

FIGURE 65.1 Algorithm for the management of CAPD-associated peritonitis. CAPD, continuous ambulatory peritoneal dialysis; MRSA, methicillin-resistant *Staphylococcus aureus*.

TABLE 65.3

Recommended Intraperitoneal Antibiotic Dosing for Catheter-Associated Peritonitis

Antibiotic	Continuous Therapy[a]		Intermittent Therapy[b]
	Loading Dose[c]	Maintenance Dose	
Cefazolin	500 mg/L	125 mg/L	15 mg/kg every 24 hr
Ceftazidime	500 mg/L	125 mg/L	15 mg/kg every 24 hr
Vancomycin	1000 mg/L	25 mg/L	30 mg/kg every 5–7 days[d]
Gentamicin	8 mg/L	4 mg/L	—
Ampicillin	—	125 mg/L	—
Clindamycin	300 mg/L	150 mg/L	—
Metronidazole	—	—	35–50 mg/kg/day PO in 3 doses

[a] Concentration dosing assumes approximately 1100 mL/m^2 or usual patient specific fill volume. The administration route is intraperitoneal unless otherwise specified.

[b] Intermittent administration should occur over ≥6 hours using one bag per day for continuous ambulatory peritoneal dialysis patients or over a full fill-volume daytime dwell for automated peritoneal dialysis.

[c] Loading dose should be administered during a 3- to 6-hour dwell period.

[d] Redosing should occur when the blood level is <12 mg/L.

Data from Warady BA, Bakkaloglu S, Newland J, et al. Consensus guidelines for the prevention and treatment of catheter-related infections and peritonitis in pediatric patients receiving peritoneal dialysis: 2012 update. Perit Dial Int 2012;32(Suppl 2):S32–S86; Chadha V, Schaefer FS, Warady BA. Dialysis-associated peritonitis in children. Pediatr Nephrol 2010;25:425–440.

Substitution of an intraperitoneal glycopeptide for the first-generation cephalosporin should be considered in patients at high risk for resistant organisms (e.g., young age, history of *S. aureus* infection, recent catheter-related infection), when local resistance of *S. aureus* to methicillin-oxacillin exceeds 10%, or the patient has a history of MRSA infection.[5,13] Double coverage using agents with different mechanisms of action is recommended if *P. aeruginosa* is suspected or isolated.[5]

Antibiotics are adjusted when culture results are available (see Fig. 65.1). If initial culture results reveal only gram-positive organisms, the third-generation cephalosporin (e.g., ceftazidime) should be discontinued. A first-generation cephalosporin should be used for methicillin-susceptible *S. aureus*, and vancomycin should be used for resistant strains. Rifampin can be considered as an additional agent in the case of documented infection with *S. aureus* or CoNS if there is a delayed response to treatment.[5] Clindamycin can be used as an alternative to vancomycin, in the absence of inducible resistance. Ampicillin is sufficient to treat most strains of *Enterococcus* and *Streptococcus* spp. Antibiotic treatment for gram-positive organisms should continue for 2 to 3 weeks.[5]

If culture and susceptibility test results identify only gram-negative organisms susceptible to ceftazidime, gram-positive coverage should be discontinued. When *Pseudomonas* or *Stenotrophomonas* is isolated, addition of a second agent is recommended.[5,54] If cultures identify anaerobic organisms or multiple gram-negative bacilli, metronidazole should be added, and an intra-abdominal source for secondary peritonitis should be sought. Antibiotic treatment should be continued for a total of 2 to 3 weeks. If the patient improves on empiric therapy and the initial cultures remain negative, the initial combination of antibiotics usually is continued for a total of 2 weeks.

Fungal peritonitis historically has been treated with intravenous amphotericin B or a combination of an imidazole-triazole (e.g., fluconazole) and flucytosine.[55] Fluconazole is considered the preferred agent (when isolated *Candida* species has proven susceptibility) over amphotericin due to superior peritoneal penetration and bioavailability.[13,56] Early removal of the peritoneal dialysis catheter is recommended due to catheter colonization, unlikely success of eradication in situ, and delayed resolution of infection.[5,3,56] If clinical improvement is observed and the dialysis catheter is not removed, antifungal treatment should be continued for an additional 4 to 6 weeks. With removal of the catheter, treatment should be continued for at least 2 weeks after resolution of clinical symptoms.[5,57] Temporary hemodialysis should be used while therapy is completed and until a new peritoneal dialysis catheter can be placed.[5,33]

With appropriate antibiotic coverage, clinical improvement (i.e., reduction in fever, abdominal pain, and cloudiness of the peritoneal effluent) should be observed within 72 hours of initiating therapy, and the dialysate aspirate should reveal a decrease in WBCs by at least 50%. Other potential sources of infection should be sought if no clinical improvement is seen with empiric treatment. In patients with excessively cloudy effluent, use of low-dose heparin (500–1000 U/L) into the dialysate can be beneficial because it decreases fibrin occlusion of the catheter.[13]

Relapsing peritonitis is defined as the recurrence of peritonitis with the same organism within 4 weeks after cessation of treatment. Empiric treatment is the same as for the initial infection, with further modifications guided by culture results. Relapsing peritonitis occurs in up to 20% of gram-positive infections initially responsive to antibiotic therapy.[58] CoNS in a biofilm secreted on the catheter surface can survive antibacterial treatment. *P. aeruginosa* produces a biofilm and can form microabscesses within the catheter tunnel. Catheter removal is not recommended universally after the first recurrence, but removal should be considered strongly with the second recurrence and in all cases associated with *Pseudomonas* species.[5] Catheter removal also is suggested when the source of reinfection is thought to originate within the catheter tunnel.[5,59] Relapsing peritonitis should be treated with intraperitoneal antibiotics for a total of 3 weeks.[59]

The recommendations for the treatment of catheter-associated peritonitis are based largely on expert opinion and convention rather than randomized, controlled trials (RCTs). Wiggins and colleagues examined 36 RCTs (i.e., 2089 adults and children) to assess the evidence for current recommendations and concluded from the available data only that intraperitoneal administration of antibiotics was superior to intravenous dosing and that use of routine peritoneal lavage or urokinase was not supported.[53] Moreover, there is considerable regional variation in the antibiotic susceptibility of pathogens, and a plan of therapy always should take into account institutional patterns of antibiotic resistance.[5,60,61]

Secondary Peritonitis

Management of peritonitis related to a ventriculoperitoneal shunt entails immediate externalization of the distal shunt, Gram stain of peritoneal fluid aspirate, and interrogation of proximal CSF. Empiric therapy is based on these findings and the time since the shunt procedure. Subsequent management of the infection and site and timing of a replacement shunt are collaborative decisions made with the neurosurgeon. Gram-negative polymicrobial infection is managed with immediate externalization of the shunt and as secondary peritonitis.

Patients with secondary peritonitis require urgent laparotomy to identify and control the source of peritoneal contamination. All infectious debris should be removed and necrotic tissue debrided. An indwelling foreign body or device should be removed. Intraoperative peritoneal irrigation may decrease the bacterial burden and reduce postoperative infectious complications, although a randomized trial suggested no benefit for routine irrigation in children with perforated appendicitis.[62] Irrigation with antibiotic solutions does not confer benefit and should be avoided.[63]

Inadequate control of the source of infection at initial laparotomy can lead to recurrent peritonitis and is associated with increased mortality and morbidity rates. Early recognition of tertiary peritonitis and having a low threshold for prompt re-exploration are critical when the possibility of continued contamination is high. This includes situations in which there is massive contamination (e.g., fecal peritonitis) or when intestinal viability is questionable at the time of abdominal closure (e.g., necrotizing enterocolitis). Mandatory re-exploration 24 to 48 hours after the initial laparotomy (i.e., second-look operation) is practiced by many surgeons and has been shown to decrease morbidity and mortality rates compared with selective re-exploration.[63]

Empiric antibiotic treatment for secondary peritonitis should cover enteric pathogens, including anaerobes and gram-negative bacilli. Treatment of secondary peritonitis with ampicillin, gentamicin, and metronidazole has long been the gold standard but usually does not confer benefit over broad-spectrum monotherapy options (e.g., piperacillin-tazobactam). Clindamycin and second-generation cephalosporins were used in the past as first-line therapy, but they should no longer be used because of the increasing resistance of *Bacteroides fragilis*.

There are no consensus guidelines for the length of antibiotic treatment after the source of infection has been controlled with operative management. However, most favor continuing therapy for 7 to 10 days after complete resolution of clinical and laboratory indicators of infection.

Complications and Prognosis

Infectious peritonitis has many life-threatening complications, including mesenteric vein thrombosis, adult respiratory distress syndrome, progressive multiorgan failure, and death. Severe complications are associated more often with secondary peritonitis, although immunocompromised children have an increased risk regardless of the source of peritonitis. Other complications include prolonged ileus, surgical wound infection, intra-abdominal abscess, enteric fistula, and inflammatory adhesions. Inflammatory thickening of peritoneal surfaces and compartmentalization of the peritoneal cavity can limit the subsequent effectiveness of peritoneal dialysis and ventriculoperitoneal shunting.

The prognosis for peritonitis largely depends on the cause of infection, associated comorbidities, and the host response to the inflammatory process. Mortality rates for healthy children who develop perforated appendicitis are very low. Mortality rates associated with peritonitis from necrotizing enterocolitis in low-birth-weight neonates remain in excess of 30% to 50%.[64] Contemporary estimates of case-fatality rates for patients receiving chronic peritoneal dialysis are approximately 6%, with peritoneal infections accounting for more than 15% of the all-cause mortality rate and 69% of the infection-related mortality rate for this cohort. Fungal peritonitis carries a particularly poor prognosis, with some series reporting case-mortality rates exceeding 25% for children.[65]

Mortality rates for primary peritonitis in children can approach 10%. They vary by cause and associated comorbidities, with an approximate rate of 9% for children with nephrotic syndrome.[66] Spontaneous peritonitis in a child with cirrhosis and portal hypertension carries a much worse prognosis, with 1-month mortality rates exceeding 30% to 40%.[67] The overall survival rate at 6 months after the first episode in these children is less than 30%, suggesting that peritonitis may be a marker of rapidly progressing hepatic dysfunction. Some experts consider the first episode of spontaneous peritonitis a relative indication for liver transplantation.

Prevention

Strategies to prevent bacterial peritonitis in children largely have focused on patients undergoing CAPD. The use of strict sterile technique during the dialysis process is crucial to prevent contamination-associated peritonitis.[5,68] Double-bag disconnect systems, which take away the need for spiking dialysis bags, have been associated with a significant reduction in peritonitis caused by touch contamination.[5,68] The competency of CAPD training appears to be critical in this regard, and studies suggest a strong correlation between the duration and quality of training and low incidence of peritonitis.[69–71]

Observational studies conducted from registry data and a few controlled trials have associated decreased rates of peritonitis and exit-site infections with specific techniques during catheter placement,[5] including the use of a double-cuffed Dacron catheter (vs. a single-cuffed model) and directing the peritoneal opening inferiorly (vs. cephalad).[5] However, a systematic review of the data by the Cochrane Collaboration failed to demonstrate a significant benefit with any specific catheter design or insertion technique on the incidence of peritonitis, tunnel-site infections, or need for catheter removal.[68]

Nasal carriers of *S. aureus* have been identified in up to 45% of families of children treated with CAPD.[72] Mupirocin applied to the nares or catheter exit site in patients and family members who are known carriers has decreased the incidence of exit-site infections and peritonitis in several studies.[73] Not all community-associated MRSA infections are susceptible to mupirocin or carried solely in the nose. Topical aminoglycoside has been used with promising results to decrease *Pseudomonas*-related infections, although resistance is a problem.[74]

Prophylactic antibiotic therapy with a first-generation cephalosporin at the time of catheter insertion significantly decreases the incidence of postoperative peritonitis.[75] Chlorhexidine scrubs decrease the density of microorganisms, including MRSA (see Chapters 2 and 100). Children with a history of MRSA colonization should receive vancomycin. A short course (i.e., 24 to 48 hours) of a first-generation cephalosporin is recommended when there is suspected contamination of the dialysate or connecting hardware and before procedures involving the gastrointestinal or genitourinary tract.[5] Prophylactic, systemic, long-term antibiotics are not indicated for patients receiving CAPD. After placement of a catheter, initiation of peritoneal dialysis should be delayed for a minimum of 2 weeks to allow wound healing, and dressing changes should be conducted by trained dialysis staff ideally no more than once per week.[76]

Appendicitis

Marion C.W. Henry, R. Lawrence Moss

Appendicitis is the most common reason for emergent abdominal surgery in children, accounting for more than one third of the hospital days for abdominal pain each year among people younger than 18 years of age in the United States.[1] Although this disease no longer is responsible for appreciable mortality, the morbidity surrounding appendicitis, particularly complicated appendicitis, can be substantial. Efforts to decrease morbidity have focused on improving methods of diagnosis, optimizing surgical management, and improving postoperative care.

Epidemiology

Approximately 80,000 US children younger than 18 years of age have appendicitis each year. Appendicitis can affect children of all ages, including infants younger than 1 year of age, but the peak incidence is among those 12 to 18 years old. There is a slight male predominance, with an 8.7% lifetime risk for boys compared with 6.7% for girls.[2] The incidence increases from 1 to 2 cases per 10,000 children younger than 4 years of age to 25 cases per 10,000 older children.[2]

There may be a modest seasonal peak in acute appendicitis during summer months, with a higher incidence of perforation in fall and winter. This pattern may reflect problems with access to care in colder months.[3] Epidemiologic factors that may increase the risk of appendicitis include a low-fiber intake and possibly the family history.[4] Approximately one third of patients with proven appendicitis have a family history of appendicitis, compared with 14% of children with right lower quadrant pain from other causes.[5]

The rate of perforation at the time of operation ranges from 20% to 95%.[6,7] The incidence of perforation decreases with increasing age, from 70% to 95% among 1- to 4-year-old children to 10% to 20% among adolescents.[4,7,8] Perforation rates are highest among minority and economically disadvantaged children and therefore in the hospitals serving these groups.[3,9–11]

Appendicitis that has advanced to perforation is associated with more severe clinical illness, higher morbidity rates, and longer hospital stays. An elapsed time of more than 36 hours from first reported symptoms to the time of surgery correlates with an increased rate of perforation.[4,12,13] Major factors contributing to a delay in surgical intervention are lack of access to care and diagnostic uncertainty.[14,15] The diagnosis of appendicitis in younger children can be particularly difficult due to the problems of recognizing the signs and symptoms in nonverbal children.

Pathogenesis

Understanding of the pathophysiology of appendicitis depends on histologic examination of surgically removed specimens.[16,17] The initiating event typically is occlusion of the lumen of the appendix between the cecal base and the tip. Occlusion can result from a foreign body such as an appendicolith, inflamed mucosa due to an infectious process, or hyperplasia of intramural lymphoid tissue. Increased intraluminal pressure then leads to swelling, congestion, and distention of the mucosa and the appendiceal wall.

Overgrowth and translocation of bowel flora leads to an acute inflammatory infiltrate in the appendiceal wall. Progressive cellulitis of the luminal wall increases intraluminal pressure. When full-thickness inflammation occurs, localized peritonitis ensues. Untreated, necrosis and frank gangrene of the appendiceal wall follows. Rupture of the appendix can then lead to expanding peritonitis and the development of an inflammatory phlegmon (i.e., intra-abdominal abscess) or generalized peritonitis. Systemic manifestations of sepsis ensue.

Etiology

The organisms responsible for appendicitis and subsequent intra-abdominal infections are those that colonize the bowel. The most commonly documented pathogens associated with appendicitis are listed in Box 66.1. In the past, a culture of the peritoneal fluid was obtained routinely at the time of operation. Studies performed 2 decades ago suggested that this practice was not cost-effective because results infrequently altered patient management.[18,19] With growing rates of antibiotic resistance, however, peritoneal cultures and susceptibility testing can have a substantial impact.[20] Rates of positive peritoneal cultures vary considerably, which can reflect differences in culture techniques or the effect of administration of antibiotics before surgical intervention.

Box 66.1

Common Organisms in Perforated Appendicitis

Escherichia coli

α-Hemolytic streptococci

Bacteroides fragilis

Bilophila wadsworthia

Peptostreptococcus species

Across case series, the most commonly isolated organisms are anaerobes: *Bacteroides fragilis, Clostridium* and *Peptostreptococcus* species, and gram-negative bacilli, including *Escherichia coli and Pseudomonas, Enterobacter,* and *Klebsiella* species. Studies have examined the microbiota of the appendix during an episode of acute appendicitis and have shown an abundance of *Fusobacterium* species in cases of appendicitis, with a corresponding absence of *Fusobacterium* species in normal appendices. Conversely, there was a reduced abundance of *Bacteroides* species. Many additional organisms found commonly in the oral cavity (e.g., *Porphyromonas* spp.) were identified in greater quantities in the specimens from patients with appendicitis.[21,22]

Clinical Manifestations, Differential Diagnosis, and Laboratory Testing

Classically, symptoms of appendicitis are periumbilical pain that migrates to the right lower quadrant, followed by nausea, occasional vomiting, and low-grade fever. The clinical presentation varies greatly, depending on the sequence of pathophysiologic events, location of the appendix in the abdomen, age of the patient, and host response to infection.

In toddlers younger than 2 years, the most common symptoms are vomiting, abdominal pain, fever, abdominal distention, diarrhea, irritability, right hip pain, and limp.[15] In children between the ages of 2 and 5 years, abdominal pain precedes vomiting and usually is associated with fever and anorexia. Tenesmus, which can be perceived as diarrhea, is common in infants and toddlers and can lead to misdiagnosis.[7] School-age children describe abdominal pain that is constant and worse with movement or coughing.[15] Nausea, vomiting, anorexia, tenesmus, and dysuria also can occur in this age group.[15] Older children sometimes report that they are hungry,[1] although anorexia is more common.

Two retrospective studies of children[23,24] and one prospective study of children and adults[25,26] determined the sensitivities and specificities of symptoms. They are, respectively, vomiting, 43% and 64%; fever, 75% and 78%; anorexia 64% and 43%; and migration of pain, 41% and 54%. In older children, the most sensitive symptom (80%) is increased pain with coughing and movement, but the specificity (52%) is low.[26]

Physical findings also vary by age. In toddlers younger than 2 years of age, nonspecific signs such as fever and diffuse abdominal tenderness are most common. Preschool children 2 to 5 years of age demonstrate right lower quadrant tenderness, fever, and involuntary guarding. School-age children are more likely to have localized right lower quadrant tenderness or diffuse guarding and rebound tenderness in cases of perforated appendicitis.[26] Two studies[27,28] found rebound tenderness in children to have low diagnostic accuracy (43%), with a sensitivity of 50% and specificity of 60%. Signs commonly equated with appendicitis such as Rovsing sign, obturator sign, and psoas sign have not been studied in detail for frequency and precision in children[26] (Table 66.1).

TABLE 66.1

Clinical Signs or Symptoms in Appendicitis by Age of Patient

Clinical Sign or Symptom	Percentage of Children with Finding by Age		
	≤2 yr	2–5 yr	6–12 yr
Abdominal pain	35–77	89–100	100
Right lower quadrant pain	<50	58–85	>90
Diffuse tenderness	55–97	19–28	15,[a] 83[b]
Vomiting	85–90	66–100	68–95
Fever	40–60	80–87	64
Anorexia	NR	53–60	47–75

[a] Without perforation.

[b] With perforation.

NR, not reported.

Other inflammatory disease, most commonly gastroenteritis, can produce signs and symptoms similar to those of appendicitis[1,29] (Box 66.2). In girls, ovarian pathology such as ruptured ovarian cyst and ovarian torsion can cause right lower quadrant pain and peritoneal irritation. In neutropenic patients, differentiating appendicitis from typhlitis or neutropenic enterocolitis can be difficult, and imaging studies often are necessary.[1,30]

Pneumonia

Primary peritonitis

Testicular torsion

Urinary tract infection

Laboratory tests often are used in conjunction with the history and physical examination to help clarify a diagnosis in children with abdominal pain. In appendicitis, the white blood cell (WBC) count typically is mildly elevated in the range of 11,000 to 16,000 cells/mm^3, but the count can be normal or elevated markedly. A markedly elevated WBC count suggests perforation or a different diagnosis. In a review of studies examining the utility of the WBC count, a wide range of sensitivity (19%–88%) and specificity (53%–100%) was found.[26]

Studies of elevated serum C-reactive protein levels show sensitivity ranging from 48% to 75% and specificity from 57% to 82% for appendicitis.[26,31] Although for adults the combination of a normal WBC count and normal CRP level makes the diagnosis of appendicitis unlikely, this is not true for children.[32] CRP levels also must be interpreted with caution for obese children because resting levels are significantly higher and the value of testing is lower in obese children.[33] In a study of serum procalcitonin levels in 212 children with appendicitis, a procalcitonin value greater than 0.5 ng/mL had a sensitivity for gangrene or perforation of 73% and a specificity of 95%.[34] However, in most children with simple acute appendicitis, the procalcitonin level was less than 0.5 ng/mL.[34]

Urinalysis results can be abnormal for children with appendicitis; pyuria and hematuria are reported in up to 30%.[35–37] Abnormal urinalysis results especially occur when the inflamed appendix is adjacent to the ureter or bladder. There are inadequate data for children to test the usefulness of urinalysis.

Diagnostic Imaging and Scoring Systems

Imaging Modalities

Plain Radiographs

In the past, plain abdominal radiographs were the most common imaging study performed for patients with suspected appendicitis. However, plain abdominal radiographs have little value, and in one study. they were normal or misleading for 82% of children with appendicitis.[15] Plain films can demonstrate a fecalith in about 5% of cases of perforated appendicitis.[1] The finding of a fecalith in a patient with abdominal pain suggests appendicitis.[38]

Ultrasonography

Ultrasonography (US) has been studied extensively as a tool for diagnosing appendicitis. Diagnostic findings include an appendiceal diameter of 6 to 7 mm, a target sign with five concentric layers, distention or obstruction of the appendiceal lumen, high echogenicity surrounding the appendix, an appendicolith, fluid surrounding the appendix, and enlarged and thickened bowel wall, and lack of peristalsis.[26] Sensitivity of US is 71% to 92%, and specificity is 96% to 98%.[39–42]

US is operator and subject dependent. Its value is enhanced by the skill and experience of the ultrasonographer and is diminished when used for patients with obesity[43] or gaseous distention of bowel loops. Even in nonobese patients, the appendix cannot be visualized in up to 30% of patients.[26]

US can be used to confirm but not rule out appendicitis.[26] In many centers, US is a first-line study due to its low cost, freedom from ionizing radiation, and superiority to clinical judgment alone in equivocal cases.[44–47] A protocol with a sequential three-step positioning algorithm can help increase sensitivity and overall accuracy.[48]

Computed Tomography

Computed tomography (CT) is considered positive for appendicitis if there is an enlarged appendiceal diameter, appendiceal wall thickening, or periappendiceal inflammatory changes, including fat streaking, phlegmon, fluid collection, and extra-luminal gas.[26] CT has a higher specificity and sensitivity than US in adults evaluated for appendicitis.[49] US studies of children have high sensitivity (94%–99%) and specificity (87%–99%).[41,49,50] Several of these studies were prospective, although not blinded, and they used a variety of techniques for administration of contrast. In many studies, many patients had clinically apparent appendicitis and an operation was already planned.

Despite high sensitivity and specificity, CT has several limitations: requirement to drink contrast and potentially to administer triple contrast, possible sedation, and exposure to contrast media and ionizing radiation. Radiation exposure from a single CT scan can subject a child to an estimated lifetime risk of 1 death from radiation-induced cancer per 1000 patients,[51] and the use of CT is increasing.[52]

There is a sustained effort to decrease radiation exposure for children. Image Gently, the Alliance for Radiation Safety in children, is a coalition of healthcare organizations dedicated to reducing radiation exposure for children, especially at dedicated pediatric facilities.[53] The CT radiation dose can be decreased without a significant impact on visualization of the appendix.[54]

Several studies have shown that CT offers no increased accuracy over history, physical examination, and laboratory analysis.[55,56] Diagnostic accuracy of clinical examination alone can be improved by repeated examinations and laboratory testing in 12 to 24 hours. Observation with serial examinations can be a cost-effective method of diagnosing appendicitis. Less than 2% of patients have perforation during such observations.[57] Some practitioners obtain an imaging study for all children with abdominal pain to reduce the rate of negative laparotomy or laparoscopy results. In addition to cost and delay, imaging has a substantial false-negative risk for a child with a high clinical suspicion of disease and false-positive risk for a child with a low clinical suspicion of appendicitis.[58] Imaging studies are most useful when restricted to children with clinically equivocal presentations.

CT may be indicated to evaluate a child with suspected complicated appendicitis because findings may influence the management strategy, directing the surgeon toward initial nonoperative therapy.[59] CT use patterns at 30 pediatric hospitals ranged from 18% to 89% in cases of suspected appendicitis.[6] One study of a selective imaging approach for equivocal cases that started with US and then used CT for inconclusive US studies showed high accuracy (97%) and cost-effectiveness,[58,60] with a sensitivity of 99% and specificity of 92%.[61] Standardized pathways and algorithms for the evaluation and diagnosis of appendicitis may decrease the use of CT and the attendant risk of ionizing radiation.[62,63]

Magnetic Resonance Imaging

Used in conjunction with US, magnetic resonance imaging (MRI) has a high sensitivity and specificity for diagnosing acute appendicitis, and it avoids ionizing radiation. Compared with other modalities, MRI has been shown to be feasible in children older than 6 years without increasing rates of perforation or negative appendectomies (i.e., removal of normal appendixes).[64–67] Using ultrafast, limited sequences, the study can be completed in 17 to 30 minutes, and children older than 5 years who can lie still tolerate the study well.

Scoring Systems

A scoring system for appendicitis was developed from a large cohort of mainly adult patients. The Alvarado scoring system was given the acronym MANTRELS based on its components (Table 66.2). Its use has been tested in children, and its name was changed to the Pediatric Appendicitis Score (PAS).

TABLE 66.2

MANTRELS Score

Feature	Description	Points
Symptoms	Migration of abdominal pain from the epigastrium to the right lower quadrant	1
	Anorexia	1
	Nausea/vomiting	1

Signs	**T**enderness of the right lower quadrant	2
	Rebound tenderness	1
	Elevated temperature	1
Investigation	**L**eukocytosis	2
	Shift to the left	1
Significance of total score	Appendicitis unlikely	<5
	Appendicitis possible	5–6
	Appendicitis likely	>6

Although some physicians found the PAS to be highly accurate,[68] most studies showed a score of ≥7 to be only moderately sensitive (76%–90%) and specific (50%–81%) for children. For adolescents older than 16 years, a score of ≥7 yields high sensitivity (100%) and specificity (93%).[26,69] Another study found PAS most useful to rule out appendicitis when the score was ≤4 and to confirm appendicitis when the score was ≥8 (both score categories negated need for imaging), with scores of 5 through 7 suggesting the need for imaging.[70] The Alvarado scoring system appears to be more useful for risk-stratifying children than for guiding clinical management.

Management

During the past 25 years, the management of appendicitis has improved. Although some aspects of care have become standardized, great variation remains.[6,71] Even within a single state, there are major regional variations in the care and outcomes of children with appendicitis.[72]

Operative Management

For cases of acute, uncomplicated appendicitis, prompt appendectomy continues to be the mainstay of treatment. Studies have suggested that appendectomy after 12 hours of preoperative antibiotic treatment does not result in increased perforation rates or clinical morbidity compared with immediate appendectomy.[73,74]

Laparoscopic and open techniques for appendectomy are used widely, with no clear outcome advantage for either. Some studies have suggested that laparoscopic procedures produce a shorter hospital course, less pain, and a better cosmetic result. A randomized trial in Europe compared differential outcomes and found only a marginal decrease in cost but a quicker return to activities for children who underwent laparoscopic appendectomy.[75] A randomized trial of the approaches in children found that compared with open appendectomy, laparoscopy was associated with less pain, shorter hospitalization, longer operating times, higher operating costs, and overall cost savings.[76]

In cases of perforated appendicitis, some studies have suggested an increased rate of intra-abdominal abscess after laparoscopy compared with open surgery.[77–82] However, a large study of four centers treating children with perforated appendicitis found no effect of surgical modality on abscess formation.[83]

Preoperative antibiotics have long been considered important in the prevention of postoperative infections. Although several studies have challenged the use of routine preoperative antibiotics, the studies were limited by small numbers of patients.[84–87] One prospective, randomized study found no difference in complication rates between patients with simple appendicitis who received antibiotics and those who did not. However, there was a significantly higher rate of infection in the one third of patients who were discovered to have gangrenous appendicitis at operation if they had not received preoperative antibiotics.[85]

A Cochrane review suggests that routine antibiotic prophylaxis for any type of appendicitis helps prevent infectious complications.[88] The Surgical Infection Society guidelines suggest that children with appendicitis routinely should be given prophylactic antibiotics preoperatively, consisting of a single agent or combination of agents that provide adequate gram-negative bacillary and anaerobic coverage.[89] In simple appendicitis, postoperative antibiotics are given for 24 hours or are not used at all. The continuation of antibiotics postoperatively in patients with perforated appendicitis is of unproven efficacy.

Many institutions have adopted clinical algorithms for the management of appendicitis. Most data used to support these algorithms are derived from retrospective reviews of pediatric populations. Examination of the benefits of using guidelines has shown a reduction in cost and length of hospital stay.[90] Some studies also reported lower readmission rates, despite an increase in disease severity, after a care pathway was initiated.[91] It is difficult to conclude what effect standardization of care has in decreasing complication rates.[92]

Nonoperative Management

Nonoperative management of appendicitis has emerged as an alternative treatment for adults with appendicitis. Several randomized, controlled studies and a meta-analysis of these studies showed a success rate of 63% with 1 year of follow-up. The risk of complications was very low, and there was no difference in the risk of developing complicated appendicitis.[93–96]

Many facilities in Europe subsequently adopted medical management as first-line management for uncomplicated appendicitis. A trial of 530 adults with uncomplicated acute appendicitis confirmed by CT who were assigned randomly to early appendectomy or antibiotic treatment found that about 25% of patients randomized to antibiotic treatment required appendectomy during a 1-year follow-up period, which was performed without significant complications.[97]

Few studies have evaluated nonoperative management of appendicitis in children. One initial retrospective[98] and one prospective, nonrandomized study[99] showed early success rates of ≥ 90% for limited numbers of children. Patients (and their parents) treated medically had fewer disability days, fewer missed days of school, and a more rapid return to their normal activities.[99] A meta-analysis of 6 randomized trials (only one performed exclusively in children) showed a pooled estimate of appendectomy rate in 550 medically managed patients to be 8.2% at 1 month and 22.6% by 12 months.[100] Further investigation is necessary to address the success, safety, and efficacy of nonoperative management beyond the first month.

Complicated Appendicitis

Most controversy and variation in the care of children with appendicitis involves complicated appendicitis. There is controversy regarding the definition of complicated appendicitis; which affects comparisons of outcomes. Some surgeons argue that gangrenous and perforated appendicitis cannot be differentiated, and there is inconsistency among surgeons in describing the severity of appendicitis.[101] The distinction is important because gangrenous appendicitis is associated with outcomes and morbidity more aligned with simple appendicitis than perforated appendicitis. The definition of perforation was developed from a prospective, randomized study.[102] Perforation was defined as a visible hole in the appendix or a free fecalith in the abdomen. Universal adoption of this evidence-based definition would enhance investigations of outcomes for cases of complicated appendicitis.

The use of nonoperative management for perforated appendicitis is controversial. In cases of peritonitis, many surgeons advocate immediate appendectomy. However, some have advocated for a treatment interval for these patients using intravenous antibiotics, followed by appendectomy.[103,104] Surgeons in favor of the latter approach cite the high rate of complications when operating during a period of intense inflammation and peritonitis. However, high failure rates for the initial nonoperative approach have been reported. If a child does not respond favorably to antibiotic therapy within 24 to 72 hours, an appendectomy is prudent. Persistence of fever for 24 hours or longer has been associated with failure of nonoperative management.[105] The nonoperative failure rate was 84% among patients whose WBC count had more than 15% bands in one study[104] and 100% with more than 10% bands in another study.[105] When the clinical course is reported in detail, patients who do not respond favorably to initial nonoperative treatment can experience high complication rates and long hospitalizations.[103,106]

The nonoperative approach may decrease morbidity for patients who come to attention with a long duration of pain or missed appendicitis.[106] A prospective, randomized trial of initial nonoperative management versus early appendectomy for children with a well-defined abscess found no difference in total length of hospitalization, recurrent abscess, dose of narcotics, or total charges.[107]

As nonoperative management of perforated appendicitis becomes more prevalent, distinguishing preoperatively between perforated and acute appendicitis becomes more critical. A scoring system has been proposed to aid preoperative differentiation of perforated from nonperforated appendicitis (Table 66.3). A cutoff score of 9 has an improved likelihood ratio and posttest probability of perforated appendicitis compared with the surgeon's diagnosis alone.[108] However, a key feature of this scoring system is the CT findings, resulting in the exposure of many patients to the adverse effects of ionizing radiation.

TABLE 66.3

Scoring System to Differentiate Ruptured Appendicitis

Finding	Points
Generalized tenderness	4
Abscess on CT	3
Symptom duration >48 hr	3
WBC count >19,400 cells/μL	2
Fecalith on CT	1

CT, computed tomography; WBC, white blood cell.

From Williams RF, Blakely ML, Fischer PE, et al. Diagnosing ruptured appendicitis preoperatively in pediatric patients. J Am Coll Surg 2009;208:819–828.

Some proponents of nonoperative management have begun to question the necessity of performing an interval appendectomy because of the insignificant rate of recurrence,[109] positing that the lumen of the appendix is obliterated after perforation. A small histopathologic analysis of interval appendectomy specimens, however, found that all specimens had a patent lumen and an appendiceal tip.[17] One randomized, controlled trial enrolling 60 patients showed a 10% recurrence rate among patients managed nonoperatively.[110] Other cohort studies have reported a similar recurrence rate.[109,111–113] In one study with an average of 7.5 follow-up years, 80% of cases recurred within 6 months, and there were no recurrences after 3 years.[113] A major limitation of these studies is the length of follow-up; the longest is 13 years. The prognosis for children into adulthood is therefore unknown. A survey of members of the American Pediatric Surgical Association found that 86% of surgeons perform an interval appendectomy for perforated appendicitis.[71]

Many surgeons have abandoned the practice of sampling pus or free fluid found during the operation for culture because results infrequently effected a change in therapy.[71] Contemporary bacteriology is not available, and emerging trends in antibiotic resistance may not be appreciated. A study from Hong Kong found that up to one fourth of bacterial species isolated from children with complicated appendicitis were not susceptible to the antibiotics selected.[20] Intra-operative peritoneal cultures will likely increasingly impact optimal antibiotic management.

In a survey of pediatric surgeons, postoperative antibiotics were used routinely,[71] but there was variation in the type and duration of antibiotics. Standard antibiotic regimens have included multidrug therapy, most frequently ampicillin plus gentamicin plus clindamycin or metronidazole. Broad-spectrum monotherapy such as with piperacillin-tazobactam likely is equally effective.[114]

Duration of therapy sometimes follows institutional protocols or is based on specific clinical factors.[71] In one randomized trial, there was no difference in infectious complications between patients given a set course of a minimum 5 days of antibiotics and those whose course was based on clinical factors with no set minimum.[115] Other studies have shown that children can be given outpatient parenteral antibiotics safely and cost-effectively[116] or can be given oral antibiotics after a course of intravenous therapy.[117,118] In one large review, there was no difference in infectious complication rates for those treated with only 3 days of antibiotics compared with those treated longer.[119]

In a prospective study, the strategy of treating with antibiotics until the child was afebrile for 24 hours and had a normal WBC count was effective.[120] A randomized trial found that completing the antibiotic course with oral antibiotics after a child was afebrile for 12 hours and tolerating a regular diet decreased the length of hospitalization without increasing the risk of postoperative abscess.[121] These clinical milestones form the basis for the duration of antibiotic therapy as proposed by the Surgical Infection Society guidelines.[89]

Traditionally, it was thought that progression of appendicitis to appendiceal rupture was within the control of the physician and that a high rupture rate reflected a failure of care. To decrease the rupture rate, early surgical intervention has been the gold standard, and high rates of negative exploration have been acceptable to decrease the likelihood of rupture. Despite many efforts to decrease the rates of complicated appendicitis, rates for children remain high and range from 30% to 74%.[10]

Later studies suggest that high rupture rates more likely reflect a delay in diagnosis and treatment because of inadequate access to medical care. In review of a national pediatric discharge database, the likelihood of perforation differed by race, even while controlling for age and health insurance status.[11] Review of a large pediatric health systems database revealed that the rate of rupture among school-aged children was associated with race and insurance status and not with the negative appendectomy rate.[10,122,123] Examination of a statewide database also revealed that children with Medicaid or no insurance were more likely to develop appendiceal perforation than those with private insurance.[122] These findings suggest a shift to focus on improved access to health care. In a large, retrospective cohort study, a low hospital volume was associated with an increased risk of misdiagnosis but not with a risk of appendiceal perforation.[11]

Intra-Abdominal, Visceral, and Retroperitoneal Abscesses

Karen A. Diefenbach, R. Lawrence Moss

Intra-abdominal abscesses that occur in children are sometimes difficult to diagnose and more difficult to treat. Even when managed appropriately, morbidity still can be high. If not managed appropriately, the results can be catastrophic. Abdominal abscesses are categorized as intra-abdominal (i.e., intraperitoneal), visceral, and retroperitoneal. Intra-abdominal abscesses are the most common type.

Bacteria from the original site of colonization or infection can travel hematogenously, pass through regional lymphatics, or spread by direct extension from a local infection to form an abscess. Intra-abdominal abscesses frequently contain mixed flora of facultative and anaerobic bacteria. In visceral and retroperitoneal abscesses, single organisms are more common. The types of bacteria isolated can indicate the origin of the infection. The most common facultative bacteria isolated in intra-abdominal abscesses are *Escherichia coli, Staphylococcus aureus,* and *Enterococcus* spp.[1,2] Anaerobic bacteria include the *Bacteroides fragilis* group, *Peptostreptococcus* spp., *Clostridium* spp., and *Fusobacterium* spp.[1,2] Enteric organisms also can cause visceral abscesses, but gram-positive bacteria of a systemic infection or fungi in immune-compromised hosts can be responsible. Retroperitoneal abscesses contain organisms specific to the site of the primary infection.[3] For example, a perinephric abscess usually is caused by organisms that cause pyelonephritis, whereas an iliopsoas abscess usually is caused by bacteremic *S. aureus*.[3–5]

The tenets of management of an abscess include drainage, appropriate antibiotic therapy, and correction, if possible, of any underlying pathology that can cause a recurrence. Drainage can be accomplished in a variety of ways, including open surgical exploration, laparoscopic surgical exploration, and percutaneous, image-guided drainage. Empiric antibiotic therapy should be initiated immediately on diagnosis considering likely abscesses by site (Table 67.1), and if necessary, it should be changed to definitive therapy when culture and susceptibility test results become available. Coordinated management by the surgical, interventional radiology, and infectious diseases specialists and by the child's primary care physician optimizes care.

TABLE 67.1

Common Organisms Found in Abscesses by Site

Site	Organisms
Intra-abdominal	*Escherichia coli, Enterococcus* spp., *Klebsiella* spp., *Bacteroides* spp., *Peptostreptococcus* spp., *Clostridium* spp., *Fusobacterium* spp., *Staphylococcus aureus,* and *Pseudomonas* spp.
Visceral (liver, spleen, pancreas)	*Staphylococcus aureus, Escherichia coli, Enterococcus faecalis, Klebsiella* spp., *Enterobacter* spp., *Pseudomonas* spp., *Streptococcus* spp., *Salmonella, Bartonella,* and *Candida* spp.
Retroperitoneal (iliopsoas, other)	*Staphylococcus aureus, Streptococcus* spp., *Escherichia coli, Klebsiella* spp., and *Candida* spp.

Intra-Abdominal Abscesses

Etiology and Clinical Manifestations

Complicated appendicitis is the most common cause of intra-abdominal abscesses in children. Patients can come to medical attention with an abscess after perforation of the appendix or can develop an abscess postoperatively.

Other intra-abdominal abscesses originate from the gastrointestinal tract, as in patients who are immunocompromised or have a chronic illness such as Crohn disease. Any operation on the gastrointestinal tract has the potential for causing a postoperative abscess. Elective operation on the bowel carries the risk of contamination of the peritoneum at the time of surgery or later from a complication such as an anastomotic leak. Emergent surgery for perforation is performed in the setting of contamination and has a higher risk of abscess formation. Other emergent causes of a perforated viscus and resultant abscess include necrotizing enterocolitis, inflammatory bowel disease, peptic ulcer, Meckel diverticulum, and trauma.[1]

Location of an abscess within the abdominal cavity, such as subphrenic and pelvic sites, can predict an underlying condition and certain pathogens. The bacteria most frequently isolated in abscesses after bowel disease or surgery include *E. coli, Bacteroides* species, and *Enterococcus* species, but any enteric organism can be present.[2] Brook studied the microbiology of intra-abdominal abscesses in children and found that 8% of cultures yielded only facultative bacteria, 17% only anaerobic bacteria, and 75% mixed flora.[1,6]

Persistence of fever and abdominal pain for 5 or more days after abdominal surgery should prompt evaluation for an abscess.[7] Early imaging may be falsely positive because of fluid collections, leading to unnecessary interventions.[7] Symptoms from compression of the abscess on adjacent structures, such as early satiety for abscesses near the stomach, urinary frequency or urgency for those near the bladder, or diarrhea or tenesmus for abscesses near the colon or rectum, associated with anorexia and weight loss are common findings in patients with abscesses.

Although uncommon, the incidence of biliary tract disease among children is increasing. Children with hemolytic disorders such as sickle cell anemia and hereditary spherocytosis are at increased risk for cholelithiasis and biliary tract disease. Although most cases of cholelithiasis in children are managed electively, some patients have complicated disease and associated cholecystitis. These patients are at risk for postoperative abscess, which should be suspected with persistence of fever and right upper quadrant pain after cholecystectomy.

Additional symptoms can include nausea, vomiting, and back or shoulder pain. The white blood cell count can be elevated, and serum hepatic enzyme levels often are abnormal. The bilirubin level usually is normal, but if elevated, it should prompt an evaluation for ascending cholangitis. Hyperbilirubinemia in children can result from obstruction of the common bile duct by a retained stone, after a Kasai procedure or liver transplantation, or from a congenital anomaly or malignancy. If identified, urgent decompression of the biliary tree is required. The serum bilirubin level also can be elevated by a bile leak postoperatively. This usually occurs at the raw surface of transplanted partial liver in the gallbladder fossa. The resulting collection of bile can become infected and require drainage. A retained gallstone or appendicolith in the peritoneal cavity after cholecystectomy or appendectomy, respectively, is another source of intra-abdominal abscess.[8] The most common pathogens associated with cholecystitis (i.e., *E. coli, Klebsiella* spp., *Pseudomonas* spp., and *Bacteroides* spp.) are considered for empiric antibiotic therapy for a postoperative abscess.

When an intra-abdominal abscess from any cause is suspected, imaging is indicated. Plain radiographs of the abdomen can show indirect evidence of abscess such as a pleural or peritoneal effusion or ileus. The diagnosis is confirmed by cross-sectional imaging. Ultrasonography (US) is preferred and can identify the location and size of an abscess in most cases, and it avoids exposure to ionizing radiation. Computed tomography (CT) should be used when US is nondiagnostic (Fig. 67.1). These studies also provide guidance for aspiration and placement of drainage catheters.

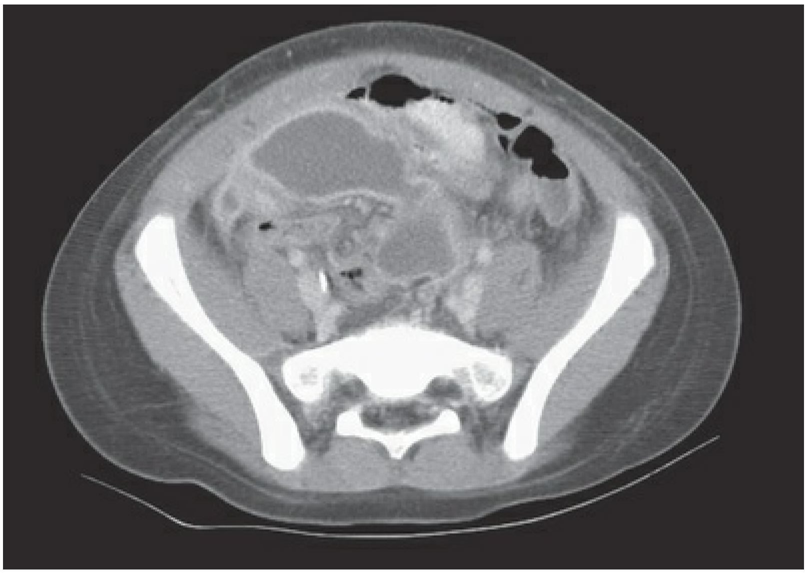

FIGURE 67.1 A postoperative abscess is visualized by computed tomography. This rim-enhancing fluid collection has the typical appearance of an abscess.

Management

Broad-spectrum antibiotics directed against facultative and anaerobic bacteria should be initiated empirically.[1,6] Therapy should be based on the location and presumed cause. Continued therapy should be guided by culture and susceptibility test results, remembering that recovery of enteric organisms also presumes an anaerobic infection. Guidelines from the Surgical Infection Society[9] recommend limiting the duration of intravenous antibiotics to 7 days if there is adequate control of the source and drainage of abscess; otherwise, parenteral antibiotic therapy may be required for an extended period.

The manner in which an intra-abdominal abscess is managed should be individualized. Antibiotics alone can be effective for fluid collections less than 5 cm in diameter or less than 20 cm^2.[10,11] Patients with a large inflammatory mass of fibrinous material with small fluid pockets are considered to have a phlegmon and usually are treated with antibiotics alone. When imaging reveals a larger fluid collection or when a smaller collection has failed to respond to antibiotics, drainage is indicated.

Percutaneous drainage under imaging guidance is standard therapy for children with abscesses (Fig. 67.2). Different modalities have been used to optimize drainage, including US or CT guidance for placement of the drain and US, fluoroscopy, or CT to reevaluate and confirm collapse of the abscess cavity.[2,12] Percutaneous drainage is desirable because it is well tolerated, is less invasive than laparotomy, and provides accurate confirmation of response to therapy[2,9–14] (Fig. 67.3). Although percutaneous drainage frequently requires general anesthesia, the risks of bowel manipulation, visceral injury, and the probability of an adhesive small-bowel obstruction are reduced.

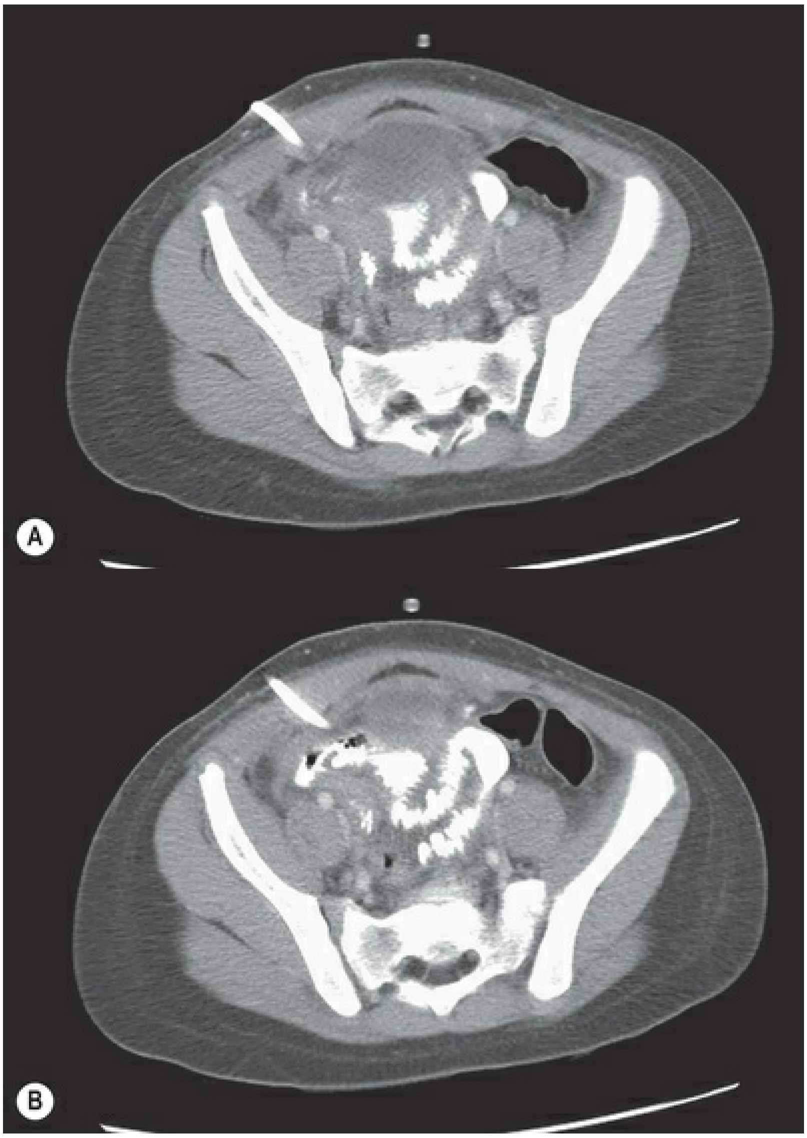

FIGURE 67.2 (A and B) Computed tomography–guided placement of a drainage catheter into the abscess.

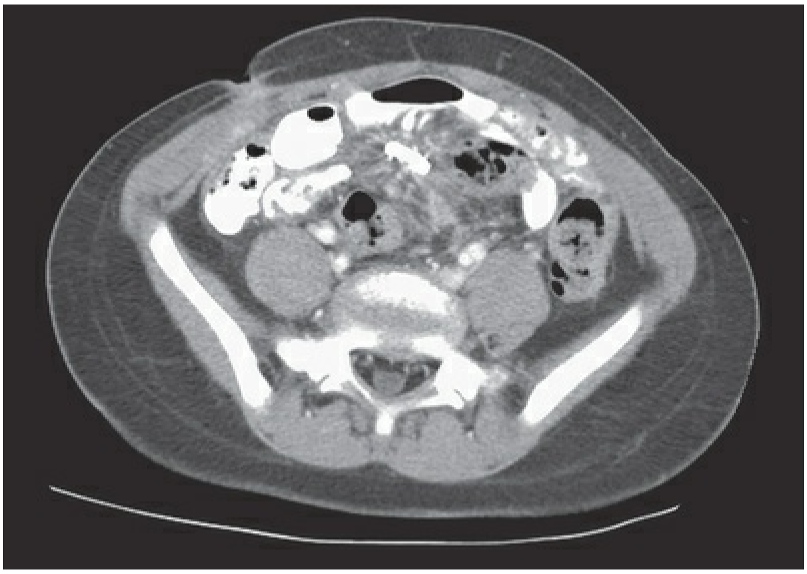

FIGURE 67.3 Resolution of the fluid collection, with the catheter visualized next to the small bowel.

The clinical setting and the location, size, organization, and number of abscesses are factored into advisability of percutaneous drainage.[12,13] Factors associated with reduced success of percutaneous drainage include complex abscesses, loculated or poorly organized abscesses, and those with multiple or extensive collections.[1,12] In one small study, abscesses with less viscous contents, as indicated by the air-fluid levels or peripheral air bubbles, were drained successfully by percutaneous methods in 95% of cases. With thicker fluid collections as evidenced by deep air bubbles, the rate of successful percutaneous drainage was 66%.[13]

Some intra-abdominal abscesses are best managed by operative or reoperative laparotomy. Indications for surgical intervention include uncontrolled septicemia, a cause of the abscess that requires surgical correction (i.e., anastomotic leak), an abscess not amenable to percutaneous drainage, and unsuccessful percutaneous drainage. Surgical drainage can be performed by open or laparoscopic technique, with no clear evidence favoring one method.[15] Several case series have demonstrated the adequacy of laparoscopy for draining abscesses.[15–18] Proponents cite better visualization of the entire abdominal contents and ability to irrigate the area adequately. In other cases, the need for a concomitant surgical procedure (e.g., to form a stoma, revise an anastomosis) is an indication for an open procedure.

Visceral Abscesses

Etiology and Clinical Manifestations

Hepatic Abscess

Before the availability of antibiotics, abscesses in the liver were often found in otherwise healthy children. Currently, most liver abscesses are seen in underdeveloped countries, in immunocompromised patients such as those receiving chemotherapy, or in children with chronic granulomatous disease or acquired immunodeficiency syndrome (AIDS).[1,19] Immunologically normal children who develop pyogenic liver abscesses usually have had a recent episode of appendicitis or cholecystitis.[20]

Pyogenic liver abscesses in children are caused by aerobic, facultative, or anaerobic bacteria, or they are polymicrobial.[1,3,21,22] Bacterial causes include *S. aureus, E. coli, Enterococcus faecalis,* and *Klebsiella, Enterobacter, Pseudomonas,* or *Salmonella* species. Cat-scratch disease also has been associated with multiple microabscesses of the liver and spleen in otherwise healthy children and in immunocompromised children with cancer or human immunodeficiency virus (HIV) infection.[1,23]

Abscesses in the liver can be single or multiple and simple or complex. They can occur as a result of direct extension from a local infection such as cholecystitis or cholangitis. They also can result from hematogenous spread through the hepatic artery or through the portal vein from sources within the abdominal cavity (e.g., associated with appendicitis). Pyelophlebitis, for example, occurs when enteric organisms access the liver through the portal system.

Amebiasis frequently is discussed as a cause of liver abscess, although some argue that the "anchovy paste" collection is not a true abscess.[1] Amebas reach the liver through the portal venous system and usually cause a single, large abscess. Other parasitic infections, including ascariasis, have been associated with hepatic abscesses. The granulomas induced by these infections are recognized predisposing factors for pyogenic liver abscesses in children in endemic areas.[20]

Traumatic injury to the liver has been associated with liver abscess in about 1% of cases.[24] Abscess associated with trauma is most common in patients managed operatively and in those with concurrent injury to a hollow viscus.

Symptoms of hepatic abscesses include fever, abdominal pain that can be diffuse or localized in the right upper quadrant, nausea, vomiting, and anorexia.[25] Jaundice is less common but can occur when the abscess compresses the biliary tract or parasitic infections (e.g., ascariasis) obstruct a bile duct lumen. The white blood cell count and serum hepatic enzyme levels can be elevated. A detailed history is important, including kitten exposure, travel in endemic areas of parasitic infestation, recent trauma, infection, and surgery.

US or CT can be used to identify abscesses. Specific antibody tests can be helpful if a parasitic infection is suspected. The hemagglutination test result usually is positive in cases of amebic abscesses, and serum antibodies for *Bartonella henselae* are detected in cases of hepatosplenic cat-scratch disease.

Splenic Abscess

The incidence of splenic abscesses appears to be increasing, although it is unclear whether this is a true increase in the number of cases or a higher index of suspicion coupled with better diagnostic tools.[26–28] Some reports indicate that the increasing number of immunocompromised patients is contributing to the changing pattern of splenic abscesses.[28] Aggressive cancer chemotherapy, the numbers of patients with HIV/AIDS, and immunosuppression for organ transplantation may be responsible.[28] Other populations at risk are patients with hemolytic disorders such as sickle cell anemia and those with a history of splenic trauma.

Splenic abscesses can be large or small and solitary or multiple. Infections can be caused by single organisms or can be polymicrobial. Organisms frequently identified include *S. aureus, E. coli,* and *Salmonella, Streptococcus, Candida,* and *Klebsiella* species.[28–31]

The triad of fever, leukocytosis, and left upper quadrant pain is common. Patients can have nausea, vomiting, and tender splenomegaly. The diagnosis can be suspected when the chest radiograph shows an elevated left hemidiaphragm or a left pleural effusion.. US, which is the preferred first study, or CT confirms the diagnosis.

Renal and Perinephric Abscess

Renal and perinephric abscesses are visceral abscesses that occur in the retroperitoneal space as a result of urogenital pathology such as pyelonephritis, urinary obstruction from a ureteral stone, or seeding from systemic infections causing bacteremia or fungemia. Renal and perinephric abscesses are discussed elsewhere (see Chapter 48).

Pancreatic Abscess

Pancreatic abscesses in children are rare and can be the result of acute pancreatitis or trauma. Injury of the pancreas due to blunt or penetrating trauma can precipitate an abscess in the setting of devitalized, necrotic tissue or a leak of the pancreatic duct. If not diagnosed preoperatively or identified at the time of exploration, the resulting fluid collection can be infected secondarily. The most common etiologic agents include *E. coli* and *Klebsiella; Enterococcus, Staphylococcus, Streptococcus,* and *Pseudomonas* species; and fungi.[32,33] The mortality rate associated with pancreatic abscesses is 15% to 50%, with morbidity rates as high as 75% to 80%.[32,33]

Symptoms include fever, epigastric or left upper quadrant pain, and hemodynamic instability. Laboratory tests show an elevated white blood cell count with some degree of serum amylase and lipase level elevation. CT with rapid contrast injection is a sensitive test that can show a nonenhancing portion of the pancreas or a fluid collection in or near the pancreas.[32]

Management

Therapy should be broad-spectrum antibiotics with activity against the most common organisms associated with the type of abscess identified. In immunocompromised patients, the addition of antifungal therapy should be considered. Decisions regarding drainage are made based on the clinical presentation, condition of the patient, and need for microbiologic confirmation.

Multiple microabscesses of the liver are treated successfully with antibiotics alone, especially in cases of cat-scratch disease.[23,25] Abscesses smaller than 4 cm in diameter can be successfully treated by aspiration, with antibiotic therapy continued until the patient's clinical status improves and CT shows resolution of the abscess.

However, in patients with abscesses larger than 4 cm or recurrence after aspiration, continuous drainage using a CT- or US-guided percutaneous catheter is indicated in addition to antibiotic therapy.[25] Surgical drainage is recommended for patients with liver abscesses that do not resolve with percutaneous drainage, those with rupture of the abscess into the peritoneal cavity, and in patients with chronic granulomatous disease who have persistent or recurrent liver abscesses.[19,25]

The management of splenic abscesses is similar to that of liver abscesses. Although salvage of the spleen is preferable and usually is possible, the primary goal is eradication of infection. Splenectomy should be considered for patients who do not respond to drainage and antibiotics. Splenectomy also should be considered for patients who are immunocompromised and have ongoing septicemia, patients with sickle cell disease or other hemoglobinopathies, those with rupture of the abscess into the peritoneal cavity, and those who have an abscess after a traumatic splenic injury.[28–31,34]

Pancreatic abscesses should be managed with drainage. In cases of pancreatic fluid collections that may not be infected or in cases of pancreatic phlegmon, CT-guided aspiration of pancreatic or peripancreatic fluid can provide specimens for culture to guide antibiotic therapy. Percutaneous drainage catheters can be left in place if the fluid appears purulent or the Gram stain is positive for organisms. Percutaneous drainage has reported success rates ranging from 69% to 86%.[33,35]

For patients who have ongoing septicemia or whose fluid collections are not amenable to percutaneous drainage, open operative exploration is required.[33,35,36] For patients who ultimately require surgery, percutaneous drainage often is a good temporizing measure for those who are too unstable to undergo surgery due to severe sepsis.

Retroperitoneal Abscesses

Etiology and Clinical Manifestations

In addition to abscesses of the kidney and pancreas, other causes of abscesses in the retroperitoneum include traumatic duodenal injury and iliopsoas abscess. Traumatic duodenal injury can be a result of penetrating trauma or blunt trauma associated with handlebar injuries of bicycles or motorcycles. Several cases of penetrating trauma to the duodenum have been reported in which retroperitoneal abscess followed the ingestion of a sharp foreign body such as a needle, toothpick, or fish bone.[37]

Abscesses associated with duodenal injuries or perforations are difficult to manage and have high morbidity and mortality rates.[38–40] Evacuation of the abscess cavity is difficult, and the underlying problem, a disruption of the duodenal wall, must be addressed to prevent further complications such as duodenal fistula.

Retroperitoneal abscess should be suspected in a patient with right upper quadrant or epigastric pain, fever, nausea and vomiting, an elevated white blood cell count, and in many cases, an elevated serum amylase level after trauma. Findings on physical examination indicating duodenal injury include a contusion of the upper abdomen with signs of peritonitis. Plain radiographs of the abdomen may not be diagnostic unless free air is detected. An upper intestinal contrast study or CT usually is diagnostic.[38,39] Organisms reported in these abscesses include *Staphylococcus* spp., *Streptococcus* spp., *E. coli, Klebsiella* spp., and *Candida* spp.[3,38,41]

Iliopsoas abscess can be primary or secondary.[42] Primary psoas abscess has no detectable source, and it is the most common type in children. Secondary abscess is associated with a known source of infection. Because the psoas muscle is intimately related to the ureter, renal pelvis, spine, appendix, terminal ileum, pancreas, jejunum, and sigmoid colon, an infectious process deriving from any of these structures can cause a secondary psoas abscess.[18,43,44] Examples include pyelonephritis, appendicitis, osteomyelitis, pancreatitis, and inflammatory bowel disease. The most common organism in primary abscess is *S. aureus,* indicating that an unidentified, mucocutaneous source leading to bacteremia is most likely.[15,43,45] Other causes include *Streptococcus pneumoniae* (the most common causative organism in patients with a history of recent respiratory tract infection) and gram-negative organisms such as *E. coli* (in patients with a history of appendicitis or other gastrointestinal infection or surgery). Underlying illness such as diabetes mellitus, HIV infection, or a connective tissue disorder increases risk in adults; case reports of psoas abscess in neonates suggest a predisposing event of femoral venous catheterization or omphalitis.[5,43,44] The most common organism is *S. aureus*, especially methicillin-resistant *S. aureus*.

Symptoms of psoas abscess include fever, leg pain or swelling, and decreased range of motion in the ipsilateral hip.[42] The degree of dysfunction of the hip joint varies from no apparent dysfunction to complete pseudoparalysis. A positive psoas sign, inguinal swelling, or lymphadenopathy can be identified on physical examination.

Septic arthritis of the hip must be differentiated from a psoas abscess. Laboratory tests often demonstrate an elevated white blood cell count and erythrocyte sedimentation rate in both conditions. Plain radiographs may reveal obscuring of the sacroiliac joint or an effusion of the hip in iliopsoas abscess, which is a sympathetic effusion due to the surrounding inflammatory process. Because a delay in treatment of pyogenic arthritis must be avoided, aspiration of the joint is the safest approach to exclude this diagnosis.[42] US is the best initial diagnostic test. It can characterize the abscess, assist in obtaining samples for culture and placement of drains, and be used to monitor resolution. CT is appropriate when US is inconclusive.

Management

Factors influencing the management of retroperitoneal abscesses resulting from duodenal pathology include time since injury, clinical presentation, hemodynamic stability, and concurrent injuries or illnesses. Any approach should accomplish drainage of the retroperitoneal abscess and address the primary pathology of the duodenum.[38–40] Possible surgical approaches include primary repair and drainage with or without pyloric exclusion and the more aggressive pancreaticoduodenectomy. Successful percutaneous drainage also has been reported.[39] Nutritional support is important because enteral feeding is precluded in the postoperative period.[38,40]

Psoas abscesses are managed by drainage and antibiotic therapy. Except in the case of a known prior infection, empiric antibiotic therapy should cover *S. aureus*, the most common etiologic agent. Drainage has been accomplished by percutaneous US-guided aspiration or catheter drainage.[46,47] Retroperitoneoscopy and open operative approaches have been used when percutaneous drainage is not successful.

Key Points

Evaluation and Management of Intra-Abdominal, Visceral, and Retroperitoneal Abscesses

- In postoperative patients, early imaging of fluid collections can lead to a false-positive interpretation as an abscess.
- To avoid radiation, ultrasonography is the preferred imaging modality for the diagnosis and therapeutic interventions.
- Although percutaneous drainage with image guidance has become a mainstay of therapy for children with abscesses, smaller abscesses (<5 cm) probably can be managed with antibiotics alone.

Superficial Bacterial Skin Infections and Cellulitis

Hillary S. Lawrence, Amy Jo Nopper

The skin has a primary protective function. It provides a permeability barrier that prevents the loss of water and electrolytes and protects against the invasion of pathogens. Intact skin is resistant to colonization and invasion of bacteria by several mechanisms.[1–3]

The outermost layer of the epidermis, the stratum corneum, constitutes the principal barrier against infection. The stratum corneum consists of corneocytes (i.e., anucleated keratinocytes or skin cells) and an outer lipid matrix. Corneocytes fit together in an overlapping fashion, making penetration by organisms difficult. Because they are shed from the skin after approximately 14 days, pathogenic organisms have a limited time to invade further into the epidermis. The lipid matrix surrounding corneocytes is acidic, providing antimicrobial activity against pathogenic organisms, including *Staphylococcus aureus* and *Streptococcus* species.[1,2]

Keratinocytes also participate in innate immunity by secretion of antimicrobial peptides (AMPs) such as human β-defensins, cathelicidin, psoriasin, and dermcidin. AMPs are small peptides with broad-spectrum antimicrobial activity against bacteria, viruses, and yeast.[2,4–6] Production of AMPs by keratinocytes is stimulated by inflammatory cytokines produced in the skin as a result of injury or inflammation and by invasive organisms through pathogen-associated molecular patterns (PAMPs).[6] Resident bacteria on the skin provide additional protection against infection by preventing colonization with pathogenic organisms through competitive binding to cell surface receptors and by the production of toxic substances called *bacteriocins* that inhibit the growth of similar bacteria.[1,3,7]

Skin microflora can be categorized as two groups: resident flora and transient flora. Resident flora establish secure attachments to the skin, are present in stable numbers, and can tolerate an acidic environment. Transient flora are introduced from the environment and attach only if the skin is disrupted.[1,8] Group A streptococci (GAS) (e.g., *Streptococcus pyogenes*) and *S. aureus* are the most common transient bacteria on the skin that cause infection.[1,3]

Many different bacteria are considered to be normal resident flora, and each organism has a predilection for specific anatomic locations and for hosts of a particular age.[1,3,7] The skin becomes colonized with microorganisms during the birth process and through contact with the environment. Infants born vaginally acquire *Staphylococcus epidermidis* during passage through the vaginal canal, and within hours, coryneform bacteria are found on neonatal skin.[1] The dry surface of the stratum corneum is colonized by micrococci and coagulase-negative staphylococci (CoNS),[1,7] whereas coryneform organisms and gram-negative bacilli prefer moist, intertriginous areas.[1,3,7,9] *Propionibacterium* spp. grow in hair follicles and sebaceous glands and are mainly found after puberty, when sebaceous activity increases.[1–3,7,9] Hair follicles are colonized by micrococci and CoNS superficially[8]; *Corynebacterium* and *Propionibacterium* spp. are found deep in follicular canals.[10]

Transient colonization of the skin by pathogens is facilitated by factors that harm the resident flora, including elevated temperature, humidity, and antibiotic therapy.[1–3,8] When a pathogen achieves successful colonization of the skin, the other cutaneous defense mechanisms must be overcome before infection commences. The main determinant of cutaneous infection is the balance between the virulence of the organism and the defense mechanisms of the host.[11] Compromised cutaneous barrier function occurs in patients with chronic dermatitis or injury and in premature infants, making their skin more susceptible to pathogenic colonization and cutaneous infection.[1]

Primary bacterial infection of the skin can involve the epidermis, dermis, or subcutaneous tissue, whereas soft tissue infections extend deeper to the fascia or muscle. Superficial skin infections are mainly limited to the epidermis and dermis; although secondary inflammation can involve the subcutis.[11] Several types of lesions can form in the skin as the result of a primary infectious process (Table 68.1), but a pathogen usually produces a characteristic primary lesion with a characteristic pattern of spread. When cutaneous bacterial infection occurs, recognition of the type and depth of lesion produced are helpful in determining the likely causative agent.

TABLE 68.1

Primary Skin Lesions

Lesion	Description
Macule	Flat lesion <1 cm
Patch	Flat lesion >1 cm
Papule	Elevated lesion <1 cm
Plaque	Elevated, broad, flat lesion >1 cm
Nodule	Dome-shaped or rounded lesion >1 cm Arises from the dermis or subcutis
Pustule	Pus-filled lesion
Vesicle	Elevated lesion <1 cm Filled with serous fluid
Bulla	Elevated lesion >1 cm Filled with serous fluid

Primary, superficial bacterial infections of the skin and cellulitis are the focus of this chapter (Table 68.2). Other infectious agents (e.g., viruses, fungi) that sometimes resemble these bacterial infections are discussed briefly.

TABLE 68.2

Primary Superficial Cutaneous Bacterial Infections

Disease	Skin Lesions	Infectious Agents
Anthrax	Papule, vesicle, bulla	*Bacillus anthracis*
Blistering distal dactylitis	Vesicle	*Streptococcus pyogenes* (group A *Streptococcus*), *Streptococcus agalactiae* (group B *Streptococcus*), *Staphylococcus aureus*
Cellulitis	Plaque	*S. pyogenes*, *S. aureus*

Diphtheria	Papule, pustule, ulcer	*Corynebacterium diphtheriae*
Ecthyma	Pustule, ulcer	*S. pyogenes*
Ecthyma gangrenosum	Papule, vesicle, ulcer, black eschar	*Pseudomonas aeruginosa*
Erysipelas	Plaque, sometimes vesicles or bullae	*S. pyogenes*, groups B, C, and G streptococci
Erysipeloid	Patch, plaque	*Erysipelothrix rhusiopathiae*
Folliculitis	Pustule, papule	*S. aureus, Malassezia* spp.
Sycosis barbae	Pustule, papule	*S. aureus*
Gram-negative folliculitis	Pustule, papule	*Klebsiella* spp., *Enterobacter* spp., *Escherichia coli, P. aeruginosa*
	Pustule, nodule	*Proteus* spp.
Hot-tub folliculitis	Pustule, papule	*P. aeruginosa*
Erythrasma	Patch	*Corynebacterium minutissimum*
Furuncles, carbuncles	Nodule	*S. aureus*
Impetigo	Vesicle, bulla, pustule, plaque, erosion	*S. aureus, S. pyogenes*
Intertrigo	Patch, plaque, erosion	*Streptococcus* spp., *S. aureus, Candida albicans, S. pyogenes*
Paronychia	Patch	Mixed flora
Perianal dermatitis	Patch	*S. aureus, S. pyogenes*
Pitted keratolysis	Erosion	*Kytococcus sedentarius, Dermatophilus congolensis, Corynebacterium* spp.
Tularemia	Papule, vesicle, ulcer	*Francisella tularensis*

Superficial Infections

Impetigo

Impetigo is a common skin infection caused by *S. aureus* and GAS. Impetigo occurs in two forms, bullous and nonbullous, and it is highly contagious. Children between 2 and 5 years of age are affected most often,[12,13] and infection rates peak in the summer and late fall.[14] Impetigo can be a primary infection or a secondary infection involving skin compromised by dermatitis or trauma.[15] Factors that predispose to infection include poor hygiene, crowded living conditions, humidity, pre-existing dermatitis, and minor skin trauma.[10,14,16]

Nonbullous impetigo is the most common form of the infection, accounting for more than 70% of cases of impetigo.[10,15] Lesions of nonbullous impetigo typically form on traumatized skin and are most often located on the exposed skin of the face and extremities.[10,12] Lesions initially begin as small vesicles or pustules that rupture, forming an adherent, honey-colored crust.[10,12,14,16,17] Impetigo is associated with minimal pain or erythema, and constitutional symptoms usually are absent. Pruritus, regional adenopathy, and leukocytosis are commonly associated with nonbullous impetigo. The differential diagnosis of nonbullous impetigo includes contact dermatitis and viral, fungal, and parasitic (e.g., scabies, pediculosis) infections, all of which can be complicated by secondary infection with impetigo. If left untreated, most cases of nonbullous impetigo resolve in approximately 2 weeks without scarring.[15]

The bacterial cause of lesions of nonbullous impetigo cannot be predicted clinically.[15] The predominant cause of nonbullous impetigo in the United States is *S. aureus,* although infection can also be attributed to GAS[10,12–14,16,18] or mixed pathogens.[14,16,18] Anaerobic bacteria have been isolated from lesions of nonbullous impetigo, although their pathogenic role is unclear.[18] *S. aureus* causes impetigo in children of all ages, and the organism usually is present in the nose, perineum, axillae, or underneath the fingernails before causing cutaneous infection. In contrast, infections due to GAS are unusual before 2 years of age, except in highly endemic areas[10]; and GAS colonizes the skin an average of 10 days before development of impetigo by inoculation of organisms into a break in the skin.[10,12] Several types of GAS can cause nonbullous impetigo, and they usually are different from strains implicated in streptococcal pharyngitis.[10]

Bullous impetigo occurs mainly in infants and young children. It is caused by strains of *S. aureus,* usually from phage group 2,[10,16] capable of producing an exfoliative toxin that disrupts cell-to-cell adhesion in the superficial epidermis, leading to superficial blister formation.[12,13,17] Because the lesions of bullous impetigo are a manifestation of localized toxin production, they develop on intact skin.[10] The flaccid bullae and pustules of this form of impetigo occur beneath the stratum corneum and are easily ruptured, leaving shallow erosions with a collarette of scale (Fig. 68.1).[10,15–17] Bullae can be single or clustered; regional adenopathy and systemic symptoms are unusual. The differential diagnosis of bullous impetigo in the neonate includes transient neonatal pustular melanosis, epidermolysis bullosa, bullous mastocytosis, and herpetic infection. Insect bites, contact dermatitis, burns, erythema multiforme, and autoimmune bullous dermatoses must be considered in older children, particularly if the lesions are unresponsive to therapy.

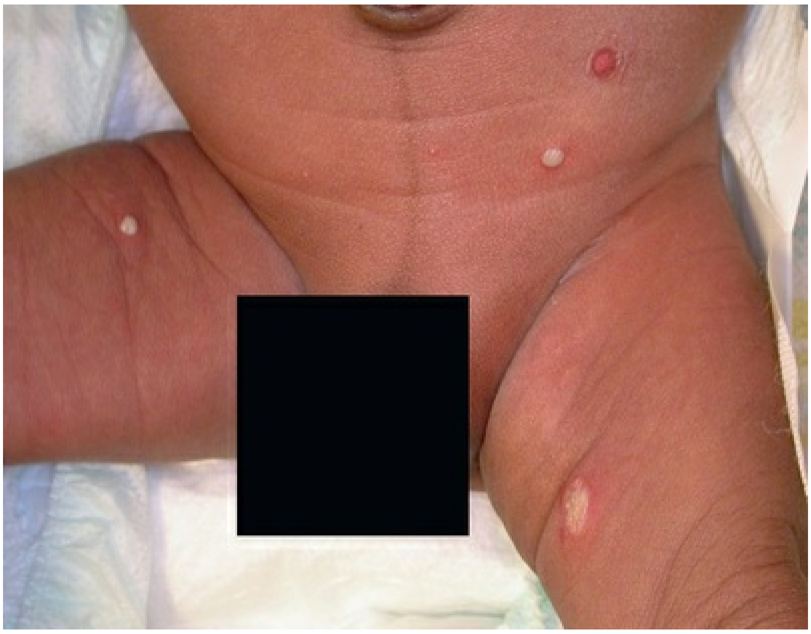

FIGURE 68.1 Scattered pustules on the abdomen and thighs of an infant with bullous impetigo caused by *Staphylococcus aureus*. One lesion has ruptured, leaving an erosion with a collarette of scale.

Complications of impetigo are rare and include invasive infections such as pneumonia, osteomyelitis, pyogenic arthritis, and septicemia. Cellulitis can complicate nonbullous impetigo but rarely is associated with the bullous form. Streptococcal impetigo can be followed by lymphangitis, suppurative lymphadenitis, scarlet fever, and acute glomerulonephritis. Acute poststreptococcal glomerulonephritis occurs after skin and pharyngeal infections with nephritogenic strains of *S. pyogenes* (i.e., M groups 2, 49, 53, 55, 56, 57, and 60 for epidemics associated with impetigo). Symptoms develop an average of 18 to 21 days after skin infection, and children between the ages of 3 and 7 years are most commonly affected.[10] The anti-DNAase B titer is the best serologic test for detecting preceding streptococcal impetigo as the cause of acute glomerulonephritis.[10,12] Strains of *S. pyogenes* associated with endemic impetigo in the United States have little to no nephritogenic potential, and acute rheumatic fever does not occur as a result of impetigo.[10]

Localized impetigo should be treated with topical antimicrobial agents. Topical mupirocin is as effective as oral erythromycin for the treatment of impetigo, and it may be associated with fewer side effects.[19,20] Retapamulin is an effective topical agent for the treatment of impetigo caused by methicillin-susceptible *S. aureus* (MSSA) and GAS. [13,21] Retapamulin applied to lesions twice daily for 5 days was found to be as effective as oral cephalexin twice daily for 10 days in treating secondarily infected skin lesions.[22] Systemic therapy is recommended for patients with widespread lesions and for lesions associated with fever or evidence of deeper involvement (e.g., cellulitis, furunculosis, abscess formation, suppurative lymphadenitis).[10] An agent effective against both *S. aureus* and GAS, such as a first-generation cephalosporin, penicillinase-resistant penicillin, or clindamycin, typically is used when systemic antimicrobial therapy is indicated.[10,12,14,17]

Antibiotic selection is based on local resistance patterns of *S. aureus*. In communities with a high prevalence of methicillin-resistant *S. aureus* (MRSA), clindamycin, trimethoprim-sulfamethoxazole, tetracyclines and fluoroquinolones are appropriate choices for systemic therapy.[15] Antibiotic therapy does not prevent acute glomerulonephritis resulting from GAS impetigo, but it does help to prevent the spread of nephritogenic strains to others.[10,12]

Patients with recurrent impetigo sometimes are evaluated for carriage of *S. aureus*. Focus on controlling density of the organism on skin and in the environment and aggressively managing skin conditions may be more beneficial than attempted decolonization.[10,23] Frequent handwashing and attention to personal hygiene should be emphasized to patients to prevent spread of infection.[14]

Perianal Bacterial Dermatitis

Perianal bacterial dermatitis usually occurs in children between the ages of 6 months and 10 years,[24] and it peaks between the ages of 3 and 5 years.[25] The infection is most commonly caused by GAS, but

S. aureus also can cause infection.[26] Physical examination characteristically reveals superficial, well-demarcated, circumferential erythema extending around the anus and surrounding skin (Fig. 68.2).[24,27,28] Vulvovaginitis with vaginal discharge and vulvar redness is common in girls, as is penile involvement in boys.[24,27] *S. aureus* is the likely pathogen when small papules and pustules on the buttocks and inguinal area are seen in addition to the characteristic findings or when there is extension of erythema onto the buttocks.[26] Additional manifestations include irritability,[28] pruritus, painful defecation (sometimes associated with refusal to defecate), blood-streaked stools, fissures, mucoid discharge, and yellow crust.[24,25,29] Familial spread of perianal dermatitis is common.[24,27] Perianal streptococcal dermatitis is reported to be an infectious trigger for guttate psoriasis, and patients with guttate psoriasis should be examined for asymptomatic GAS infection.[29]

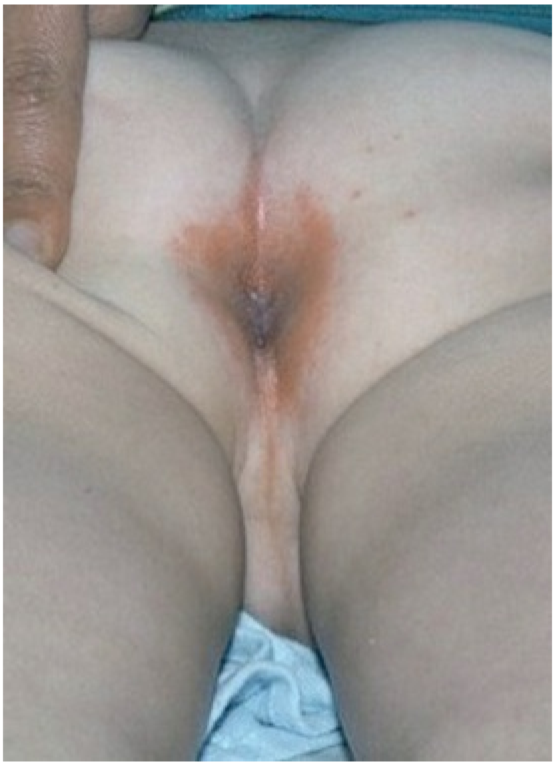

FIGURE 68.2 Brilliant erythematous perianal dermatitis due to group A *Streptococcus*.

The differential diagnosis of perianal bacterial dermatitis includes psoriasis, irritant contact dermatitis, candidiasis, and pinworm infestation. Diagnosis of perianal bacterial dermatitis often is delayed due to misdiagnosis and lack of awareness of the condition,[25] with patients frequently undergoing treatment with topical antifungal agents or topical corticosteroids before the correct diagnosis is made.[24,25] Isolation of *S. pyogenes* or *S. aureus* from culture of perianal swab specimens confirms the diagnosis.[24]

Therapy should be guided by culture results and susceptibility test results. Penicillin is recommended for cases due to GAS; recurrence rates of up to 39% were reported previously,[30] but the rate was only 12% in a recent study.[31] Clindamycin, a β-lactamase resistant penicillin, or a cephalosporin may be useful in cases due to *S. aureus.* A topical antibiotic or erythromycin and mupirocin may be effective as solitary treatment but typically are used as an adjunct to systemic therapy.[32]

Intertrigo

Intertrigo is a disorder of the skinfolds resulting from the friction created by opposing skin surfaces combined with a moist environment. Infants are particularly susceptible to intertrigo because they have deep skinfolds, a flexed posture, chubbiness, and a tendency to drool.[33] Secondary infections with *Candida albicans,* GAS, *S. aureus,* and mixed organisms can occur. Bright red, well-demarcated, weeping patches and plaques are seen in the folds of the neck, axillae, antecubital fossa, inguinal area, or popliteal fossae (Fig. 68.3). Satellite lesions suggest *Candida* infection, whereas streptococcal intertrigo commonly is associated with a foul odor. Affected infants usually appear well but can have associated fever, fussiness, or malaise.[33,34]

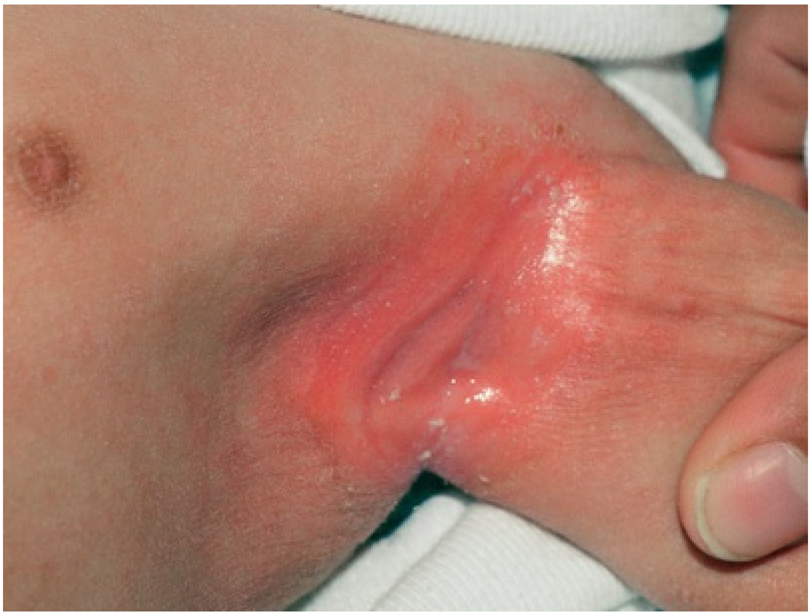

FIGURE 68.3 Erythematous weeping patch of intertrigo in the axillae of a 2-month-old girl, who had similar lesions on the fold of her neck and inguinal creases. Bacterial culture of the lesion grew group A *Streptococcus* and *Staphylococcus aureus*.

The differential diagnosis of intertriginous dermatitis includes seborrheic dermatitis, atopic dermatitis, irritant or allergic contact dermatitis, erythrasma, inverse psoriasis, scabies, and Langerhans cell histiocytosis. The diagnosis is confirmed by culture of a lesion.

Treatment of candidal intertrigo consists of topical antifungal agents such as nystatin, econazole, or ketoconazole, whereas streptococcal intertrigo can be treated with a 10-day course of penicillin or cephalexin in combination with topical mupirocin. Anti-inflammatory agents (e.g., topical 1% hydrocortisone) can be used for associated erythema. Using barrier ointments and ensuring that skinfolds are completely dry reduces the friction and moisture of intertriginous areas, helping to prevent intertrigo.[33]

Erythrasma

Corynebacterium minutissimum is the causative agent of erythrasma. This cutaneous infection manifests as well-demarcated, reddish brown patches and plaques located in moist intertriginous zones. Infections usually occur after puberty. The condition may be asymptomatic or associated with pruritus, and involved skin may be thin with a “cigarette paper” quality.[35] Commonly affected sites include the groin, axillae, intergluteal folds, submammary region, and interdigital spaces of the toes. Heat, humidity, obesity, diabetes mellitus, hyperhidrosis, and poor hygiene are predisposing factors.[35,36]

Erythrasma can be confirmed with a Wood lamp examination. *C. minutissimum* produces porphyrins that fluoresce a brilliant coral-red color under ultraviolet light. However, bathing within 20 hours before the Wood lamp examination can remove the water-soluble porphyrins. When the Wood lamp examination result is negative, a potassium hydroxide examination is useful to exclude dermatophyte infection. Skin scrapings can be stained with periodic acid–Schiff, methenamine silver, or Gram stain to assess for coccobacilli.[35]

The treatment of choice is erythromycin (250 mg four times daily for 2 weeks). Topical clindamycin twice daily also can be used.[36] A single dose of clarithromycin (1g) is reportedly effective for erythrasma in adults.[37]

Pitted Keratolysis

Pitted keratolysis is a skin infection affecting the thick stratum corneum of the plantar surface of the feet and less commonly the palms. Characteristic findings include white, hyperkeratotic areas studded with multiple. 1- to 7-mm, pitted or erosive lesions on the soles, particularly over pressure-bearing sites (Fig. 68.4).[35,38] Ringed erythematous lesions that coalesce can be seen on nonhyperkeratotic areas.[35] The condition can be asymptomatic or associated with hyperhidrosis, foul odor due to production of sulfur compounds, pain, and sliminess of the skin. People whose feet are moist for prolonged periods due to hyperhidrosis, immersion in water, or use of occlusive shoes are affected most frequently. Males are affected more often than females.[35,38,39]

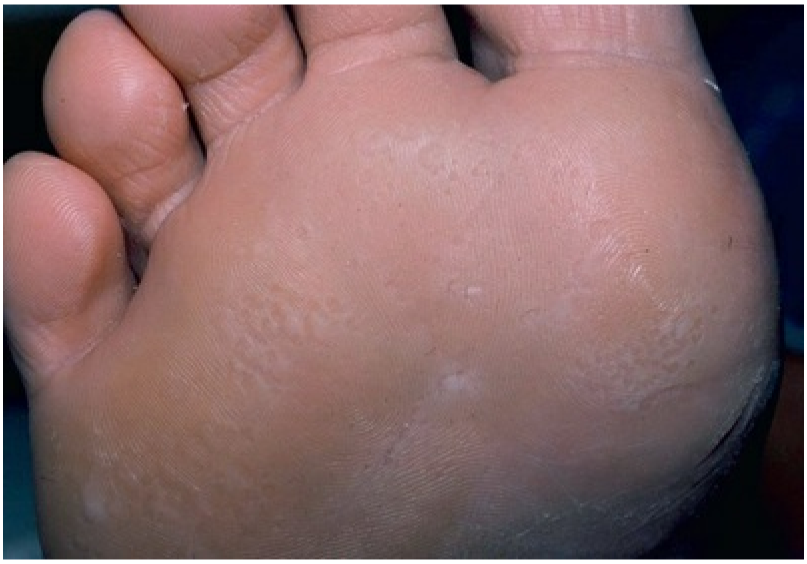

FIGURE 68.4 White plaques with numerous shallow pits on the plantar surface of the foot of a patient with pitted keratolysis.

Kytococcus sedentarius (formerly *Micrococcus* spp.), the suspected causative agent of pitted keratolysis, produces serum proteases capable of degrading keratin in calloused skin.[40] *Dermatophilus congolensis* and *Corynebacterium* spp. also have been implicated as pathogens.[35,38] The diagnosis is based on characteristic clinical findings.

Effective therapeutic regimens include topical therapy for 2 to 3 weeks with erythromycin, clindamycin, mupirocin, benzoyl peroxide, or fusidic acid. Control of hyperhidrosis with topical aluminum chloride or botulinum toxin, improved hygiene, and use of adequately fitting shoes may also help.[35,39]

Trichobacteriosis

Trichobacteriosis (formerly trichomycosis) is an asymptomatic infection of the axillary and less commonly the pubic hair shafts caused by *Corynebacterium flavescens* and other coryneform species.[35,41,42] A bacterial biofilm encases the hair, creating yellow or white concretions distributed along the length of the hair shaft. Hyperhidrosis and a foul odor can be associated with the condition.

The diagnosis is clinical, although a pale yellow fluorescence may be seen with a Wood light examination. Treatment consists of shaving the affected area, applying topical antibiotics (e.g., clindamycin, erythromycin) and use of antiperspirants to control hyperhidrosis.[31,42]

Adnexal and Follicular Infections

Folliculitis

Bacterial folliculitis is a superficial infection of the hair follicle that manifests as discrete, 2- to 5-mm papules and pustules on an erythematous base. The lesions can be single or grouped, and a hair shaft often is seen in the center of the lesion (Fig. 68.5).[17] Lesions usually are located on the scalp, buttocks, or extremities,[15,17] but they can occur on any hair-bearing area.[15]

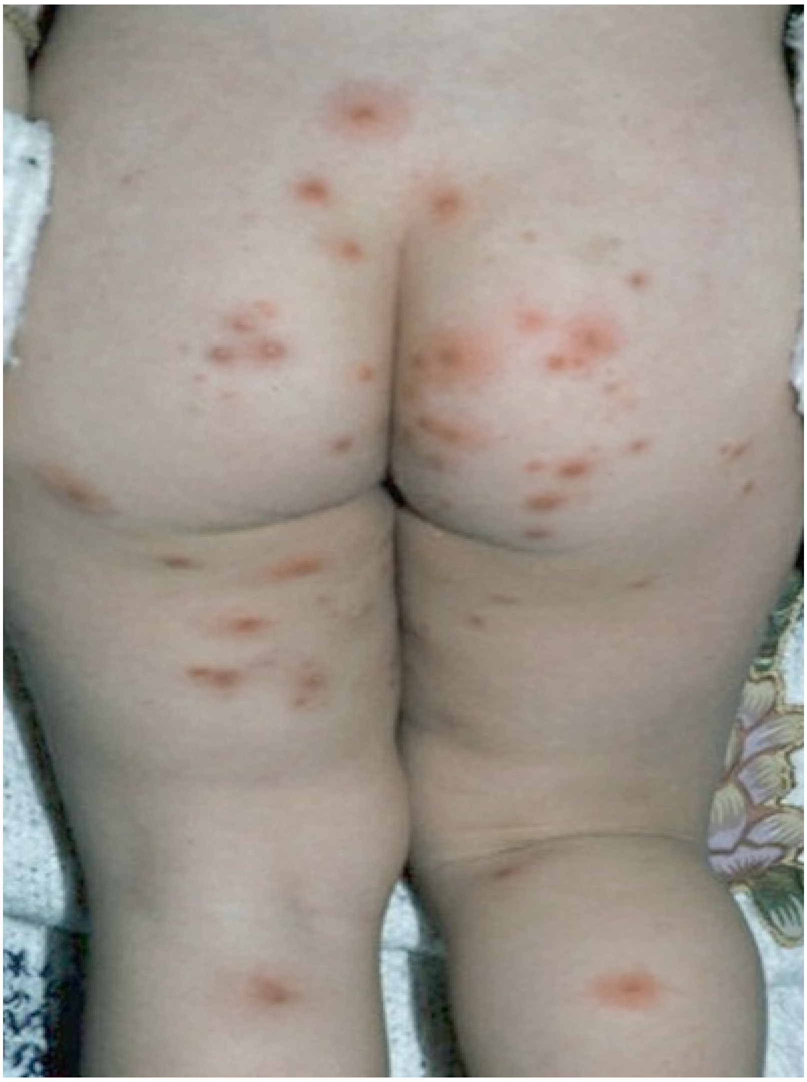

FIGURE 68.5 Erythematous follicular papules and pustules on the buttocks and posterior legs of a young child with folliculitis due to *Staphylococcus aureus*.

Folliculitis can be asymptomatic or accompanied by pruritus; systemic symptoms usually are absent.[17] Gram stain and culture of purulent material from the follicular orifice can identify the causative organism of folliculitis. *S. aureus* is the predominant pathogen,[15,17,43] and affected patients often are chronic carriers of *S. aureus* in the nares, perineum, or axillae.[43] However, gram-negative bacteria also can cause folliculitis (discussed later). The differential diagnosis of bacterial folliculitis includes inflammation of the hair follicle due to physical injury or chemical irritation, eosinophilic folliculitis, insect bites, scabies, pseudofolliculitis barbae, and infection due to *Malassezia* species.
